DEFINITION AND SCOPE OF ENDOCRINOLOGY

The term *endocrine* was coined by Starling to contrast the actions of hormones secreted internally (endocrine) with those secreted externally (exocrine) or into a lumen, such as the gastrointestinal tract.[1] This terminology continues today but makes the specialty somewhat opaque to the general public, who are more familiar with the term *hormone* and with particular disorders of the endocrine system. The term *hormone* is derived from the Greek verb *hormao,* which means "to set in motion." This phrase captures the dynamic properties of hormones and their ability to elicit a cascade of physiologic responses by acting on specific target tissues. Reminiscent of Newton's third law of motion, which states that "for every action, there is an equal and opposite reaction," hormone action is typically counteracted by physiologic responses that restore the system to equilibrium.

The major physiologic processes controlled by hormones include (1) growth and maturation, (2) intermediary metabolism, and (3) reproduction. However, the clinical specialty of endocrinology is most clearly delineated by diseases that afflict the classic glands, that is, hypothalamus, pituitary, thyroid, parathyroid, pancreatic islets, adrenal gland, testis, and ovary. In various parts of the world, additional clinical disorders, such as hypertension, nutrition, obesity, osteoporosis, and hyperlipidemia, also fall within the scope of endocrinology.

The basic science of endocrinology has evolved from studies of hormone identification and structure to a greater focus on hormone action. Concepts of receptors and intracellular signaling, as well as many aspects of transcriptional regulation, remain an essential component of the field. Endocrinology is ultimately the study of intercellular communication. In some cases, communication occurs within the same tissue, as exemplified by autocrine and paracrine actions of insulin-like growth factor-1 (IGF-1). More classically, hormones mediate communication between organs, as exemplified by the actions of parathyroid hormone (PTH) on bone or kidney. In this era of genomics, proteomics, and metabolomics, the traditional lines that separate endocrinology from other physiologic disciplines are becoming blurred. Erythropoietin is a classic hormone. Because it is produced by the kidney and regulates erythrocyte production, erythropoietin's clinical role is relevant primarily to the fields of nephrology and hematology. Similarly, blood cell–stimulating factors such as granulocyte colony-stimulating factor (G-CSF) are studied and used by hematologists and oncologists. The receptors for colony-stimulating growth factors such as G-CSF and granulocyte-macrophage colony-stimulating factor are, however, members of a superfamily that includes the growth hormone (GH) and prolactin (PRL) receptors. These receptors share similar intracellular signaling systems, including the Janus kinase (JAK)–signal transduction and activators of transcription (STAT) pathway. Growth factors with more pleomorphic functions, such as cytokines, are being investigated and used in almost every specialty.

Principles of endocrinology are readily transferable to other clinical disciplines. For example, hormones play a crucial role in blood pressure maintenance, intravascular volume regulation, and peripheral vascular resistance tone in the cardiovascular system. Angiotensin II, catecholamines, endothelins, and other vasoactive substances act via specific receptors to mediate dynamic changes in vascular tone. The heart produces hormones, such as atrial natriuretic peptide, in response to volume overload, resulting in compensatory natriuresis. The gastrointestinal tract is a remarkably rich source of peptide hormones, such as ghrelin, gastrin, glucagon-like peptide, cholecystokinin, secretin, and vasoactive intestinal peptide, among many others. Some of these factors, such as ghrelin and cholecystokinin, modulate appetite and perform local actions in the gastrointestinal tract; others, such as gastrin and secretin, act mainly in the gastrointestinal tract to induce physiologic responses to meals.

With the discovery of new hormones (e.g., PTH-related peptide, leptin, ghrelin, activin, atrial/brain natriuretic peptide, fibroblast growth factor 21, fibroblast growth factor 23), the scope of investigative and clinical endocrinology continues to expand. In addition, many areas of traditional endocrinology have been "spun off" and transformed into other disciplines. For example, although hypothalamic regulation of the pituitary gland remains a core element of endocrinology, neuroendocrinology is rapidly becoming a distinct discipline. Similarly, calcium regulation is inextricably linked to bone metabolism. Some bone disorders, such as osteoporosis or rickets, are treated mainly by endocrinologists, whereas others, such as renal osteodystrophy or phosphate wasting disorders, are often managed by nephrologists. Reproductive endocrinology has become a subspecialty of gynecology and urology, primarily because of the skills needed to perform procedures related to the evaluation and treatment of infertility. Ovulation induction protocols and various forms of assisted reproductive technology are increasingly used to manage infertility, which affects 10% to 15% of reproductive-age couples. Intracytoplasmic sperm injection has revolutionized the approach to male infertility. A new discipline of "oncofertility" addresses the need for fertility preservation in women, as well as men, with cancers that occur during the reproductive time frame. Common endocrine diseases, such as autoimmune thyroid disease and type 1 diabetes mellitus, are caused by abnormal regulation of immune surveillance and tolerance. Less common diseases, such as polyglandular failure, Addison disease, and lymphocytic hypophysitis, also have an immunologic basis. Although immunology is an independent discipline, the interface with endocrinology is important for understanding the pathogenesis of these disorders. Cytokines and interleukins have profound effects on the functions of the pituitary, adrenal, thyroid, and gonads. Thus, the boundaries of endocrinology change constantly, spawning new disciplines and expanding into new scientific realms.

KEY POINTS

- Although individual hormones regulate specific physiologic processes, such as growth, metabolism, and reproduction, they typically act in a concerted or integrated manner with other hormones.

HISTORICAL PERSPECTIVES

Although concepts of fertility and reproduction can be traced to ancient times, most of our current understanding of endocrinology has evolved during the past 150 years.[2] The structures of the major glands and ducts were initially captured in drawings by Renaissance anatomists and artists. The publication of *De Humani Corporis Fabrica* in 1543 by Vesalius provided a turning point in studies of human anatomy. Fallopio, also of the Padova School, published *Observationes Anatomicae* in 1561, which included a detailed description of the "slender and narrow seminal passage that arises from the horn of the uterus."

A timeline for selected advances in endocrinology is depicted in Figure 1.1. Berthold recorded the physiologic consequences of castration in 1849. He demonstrated that castration of a cock caused regression of secondary sex characteristics and mating behavior. Transplantation of the testes into the abdominal cavity restored these features, proving a role for the gonads in sexual differentiation and illustrating basic principles of hormone withdrawal and replacement. In 1855, Claude Bernard noted that the liver produced two secretions, an external secretion (bile) and an internal secretion (glucose), which passed directly into the circulation. This concept was later extended by Bayliss and Starling, who discovered that secretin, a substance extracted from duodenal mucosa, induced pancreatic exocrine secretion after intravenous injection. This observation distinguished the properties of circulating hormones from physiologic reflexes mediated by the nervous system.

In the late 1800s, the clinical manifestations of many endocrine disorders were described. The Report on Myxedema by the Clinical Society of London (1888) is a remarkable example of the power of astute clinical observation. In addition to recognition that the adult disorder of myxedema shared certain clinical features of cretinism,[3] a tenuous connection to thyroid gland dysfunction was proposed. The plates shown in Figure 1.2 illustrate some of the clinical manifestations of hypothyroidism as described by William Ord, who coined the term *myxedema* (mucinous edema).[4] Several years later, George Murray tested the role of the thyroid gland in myxedema by demonstrating that repeated subcutaneous injections of sheep thyroid extract corrected the disorder.[5] This was probably the first example of successful hormone replacement and spawned parallel efforts for other glandular diseases. By the turn of the century, the clinical manifestations of Graves disease, acromegaly, Addison disease, diabetes mellitus, and pheochromocytoma were well established. Hormone isolation and replacement strategies became a major research effort, culminating in the characterization of corticosteroids, thyroid hormones, and sex steroids. The history of endocrinology is replete with colorful renditions of hormone isolation and discovery. A recurring theme is teamwork and parallel observations by different teams working on the same problem—a testimony to the impact of scientific communication and the need for technology to drive advances.

The discovery of insulin in 1921 has been chronicled extensively and is a true inflection point in endocrinology.[6] The pancreatic islets are clusters of endocrine cells that are embedded within the exocrine pancreas. Early experiments in dogs by Minkowski[7] showed that pancreatectomy caused diabetes, demonstrating the pancreas as the organ responsible for regulating glucose. Banting and Best set out to isolate insulin, a process that was greatly aided by the expertise of Collip, a

Plates taken from serial photographs of a woman with untreated hypothyroidism. Plate 1: At 21 years of age, before onset of myxedema. Plate 2: At 28 years of age, showing early features of myxedema. Plate 3: At 32 years of age, illustrating overt features of myxedema. (From *Clinical Society of London report on myxedema.* Boston: Francis A. Countway Library of Medicine; 1888. Photographs originally published in Ord WM. On myxoedema, a term proposed to be applied to an essential condition in the "cretinoid" affection occasionally observed in middle-aged women. *Medico-Chirurgical Trans.* 1978;61:57–78.)

protein chemist who isolated several other peptide hormones, including PTH.[8,9] Despite erratic initial results in diabetic dogs, Banting and Best soon achieved unequivocal success using partially purified insulin. At the time of insulin isolation, children with type 1 diabetes had no treatment options aside from starvation therapy, which could not prevent their ultimate demise from hyperglycemia and ketoacidosis. The initial insulin treatment results were stunningly successful, providing immediate clinical benefits soon followed by the ability to achieve long-term management with repeated use of insulin injections (Fig. 1.3). This dramatic treatment strategy was stymied initially by the limited supply of purified insulin, a problem that ultimately was solved by the development of recombinant human insulin. In this current era, pancreas and islet transplantation represent alternative treatment approaches. However, limited human donor tissue and ongoing challenges with immunosuppression have restricted the use of transplantation to patients with severe type 1 diabetes. There is hope, however, that stem cell biology or the ability to regenerate pancreatic islet β cells might ultimately overcome these limitations.

Recognition that the hypothalamus produces a variety of pituitary regulatory factors was another major advance. In addition to establishing a link between the brain and the "master gland," the hypothalamic-pituitary system underscored the critical importance of anatomic proximity and vascular delivery for the regulation of hormone action. It is now appreciated that discrete pulses of hypothalamic gonadotropin-releasing hormone (GnRH), GH-releasing hormone, thyrotropin-releasing hormone (TRH), and corticotropin-releasing hormone (CRH) act locally on the pituitary gland and exert little, if any, physiologic effect at more distal sites in the body.

Following the isolation of many steroid and peptide hormones during the first half of the twentieth century, a conceptual framework was outlined for mechanisms of hormone action. For peptide hormones, Sutherland established the idea of a second messenger system in which a hormone binds to a membrane receptor, thereby activating intracellular second messenger pathways such as cyclic adenosine monophosphate (cAMP).[10] For steroid and thyroid hormones, Tata established the concept of hormone action at the nuclear level, acting via intracellular receptors that altered gene expression, which in turn caused changes in protein levels.[11] The development of the radioimmunoassay (RIA) by Berson and Yalow revolutionized endocrine physiology and diagnosis by allowing accurate measurement of minute amounts of circulating hormones.[12] The impact of RIA on physiology, endocrinology, and clinical medicine cannot be overemphasized. RIA and related assays are now used routinely for almost all hormone measurements and have replaced many less-sensitive chemical methods and bioassays. RIA was once the province of specialty endocrine laboratories but has gradually become automated and integrated into clinical pathology laboratories. Mass spectroscopy methods are being used increasingly as a means to measure steroids and peptides. These methods not only are sensitive and highly quantitative, but also do not necessarily depend upon antibodies to detect specific molecules.

Important advances in therapeutic modalities have accompanied our improved understanding of endocrine diseases. Hormone replacement strategies have been refined, along with advances in surgical approaches for endocrine tumors. Many hormone excess syndromes are primarily managed surgically, including transsphenoidal surgery for pituitary tumors or excision of parathyroid, adrenal, and pancreatic tumors. Many glandular surgeries are now performed via minimally invasive techniques, such as laparoscopy or video-assisted resection through very small incisions. In addition to hormonal replacements, important medical therapies that have been developed include the use of radioactive iodine[13] and antithyroid drugs[14] for hyperthyroidism, dopamine agonists for prolactinomas,[15] somatostatin analogues for acromegaly, oral hypoglycemics for diabetes,[16] gonadal steroids as

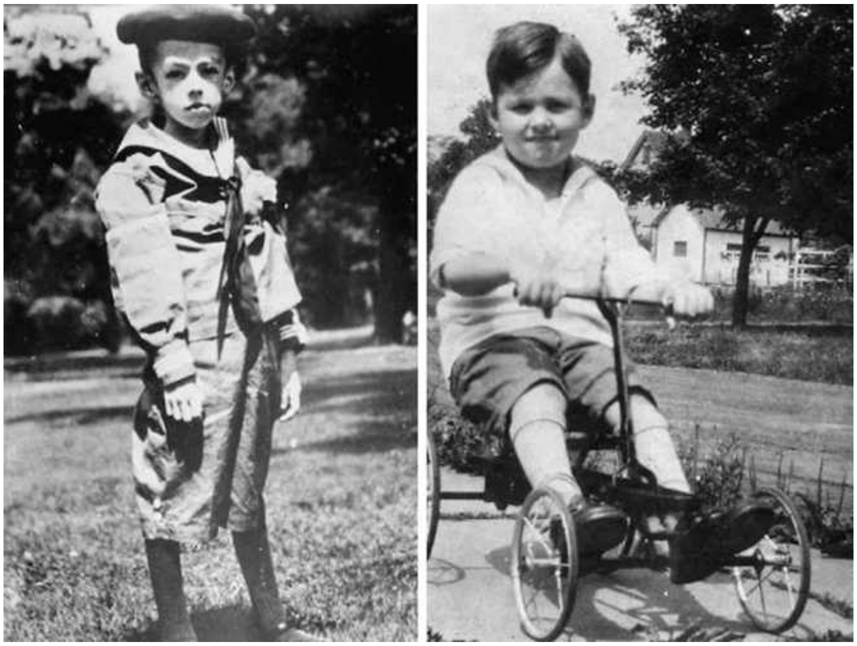

Fig. 1.3 Treatment of type 1 diabetes mellitus with insulin. Teddy Ryder was one of the first patients treated by Dr. Banting. After undergoing "starvation treatment" *(left panel),* which was the only therapy available at the time, he began insulin treatment at 5 years of age (July 10, 1922) *(right panel).* One year later (July 10, 1923), he is seen "cured." Teddy Ryder lived to 76 years of age. (Modified with permission from the University of Toronto Libraries Discovery and Early Development of Insulin online collection, http://digital.library.utoronto.ca/insulin/.)

contraceptives,[17] and somatostatin analogues for tumors of the gastrointestinal tract.[18]

In recent years, the tools of molecular genetics have dramatically accelerated our understanding of endocrinology. DNA sequences encoding hormones such as somatostatin,[19] GH,[20] insulin,[21] and chorionic gonadotropin[22] were among the first human complementary DNAs (cDNAs) cloned. Recombinant DNA techniques are now used routinely to identify new hormones and receptors and to elucidate hormone function.

Hormone genes have provided important models for understanding mechanisms of transcriptional regulation. Hormones typically are expressed in a cell-specific manner (e.g., GH, thyroglobulin), providing prototypes for identifying transcription factors (e.g., Pit-1, TTF-1) that restrict expression to particular cells or tissues. Hormone-regulated pathways have provided experimental variables that can be switched on or off, thereby revealing highly regulated target genes that can be used as experimental models. Thus, studies of the cAMP signaling system have unraveled the protein kinase A cascade and transcription factor targets, such as cAMP response element binding protein. Nuclear receptor pathways have been particularly illuminating. In addition to identifying target genes regulated by hormones such as estrogen, glucocorticoid, or thyroid hormone, detailed analyses of these pathways have helped to define how DNA binding specificity is encoded in promoters and how transcription factors suppress or enhance gene expression by recruiting corepressor or coactivator complexes. Transcription by nuclear receptors is arguably the best understood paradigm for how transcription factors initiate transcription, assemble a transcription complex, and renew the process to ensure multiple rounds of RNA synthesis. The genetic basis for several hundred endocrine disorders has been determined through the use of molecular biological approaches, and these tests are being used increasingly in clinical practice.

In addition to technical advances such as RIAs and recombinant DNA technology, endocrinology has contributed disproportionately to pivotal conceptual advances in science and medicine. Almost every aspect of physiology is tied to rhythms. The endocrine system has provided models for rapid rhythms such as luteinizing hormone (LH) or GH pulsatility, circadian rhythms such as cortisol or vasopressin production, and longer rhythms such as the menstrual cycle or bone remodeling. Concepts of hormone–receptor interaction and second messengers established signal transduction paradigms that proliferated into innumerable signaling networks. Polypeptide precursors, such as pro-opiomelanocortin (POMC), preproglucagon, preproparathyroid hormone, and others established pathways for protein processing, transport, and secretion. Studies of growth factors helped to refine concepts of autocrine and paracrine action, which can be viewed as an extension of classic endocrine action. Hormone replacement formed the foundation for the use of biologic agents such as factor VIII, G-CSF, and erythropoietin. The genetic basis for cancer has been elucidated by studies of the multiple endocrine neoplasia syndromes, types I and II.

KEY POINTS

- The field of endocrinology has pioneered many technological advances, including protein sequencing, RIAs, ligand–receptor interactions, and recombinant DNA technology, including the large-scale synthesis of hormones such as insulin or GH.

PRINCIPLES OF HORMONE ACTION

The principles of hormone action include fundamental concepts such as hormone biosynthesis and secretion, feedback regulation, hormone–receptor binding, and initiation of intracellular signaling. These principles are broadly applicable to other subspecialties in addition to endocrinology.

Hormone Biosynthesis and Secretion

Hormones can be divided into five major classes: (1) amino acid derivatives such as dopamine, catecholamines, and thyroid hormone; (2) small neuropeptides such as GnRH, TRH, somatostatin, and vasopressin; (3) large proteins such as insulin, LH, and PTH that are produced by classic endocrine glands; (4) steroid hormones such as cortisol and estrogen that are synthesized from cholesterol-based precursors; and (5) vitamin derivatives such as retinoids (vitamin A) and vitamin D. As a rule, amino acid derivatives and peptide hormones interact with cell-surface membrane receptors. Steroids, thyroid hormones, vitamin D, and retinoids are lipid-soluble and interact with intracellular nuclear receptors.

Many peptide hormones are produced from precursor polypeptides. Characteristic signal or leader sequences target these peptides for extracellular transport via secretory granules. Some precursors, such as POMC or preproglucagon, encode multiple biologically active peptides that are generated by specific processing enzymes; other precursors, such as preproinsulin and vasopressin, encode single hormones that are excised from larger proteins. The secretion of peptide hormones is tightly controlled by intracellular signals that regulate vesicle transport and fusion with the plasma membrane, resulting in hormone release into the extracellular milieu. Steroid hormones such as progesterone, cortisol, and testosterone are synthesized from cholesterol derivatives through a series of enzymatic steps. These enzymes are expressed specifically in steroidogenic tissues such as the adrenal gland and gonads. Their enzymatic activities are regulated in response to trophic hormones such as adrenocorticotropic hormone (ACTH), LH, or follicle-stimulating hormone (FSH). Thyroid hormone is produced by modifications (iodination) of tyrosines in thyroglobulin. Vitamin D and retinoic acid are derived in part from dietary sources but can also be generated and activated by endogenous synthetic pathways.

KEY POINTS

- Hormones can be divided into five major classes: (1) amino acid derivatives such as dopamine, catecholamines, and thyroid hormone; (2) small neuropeptides such as GnRH, TRH, somatostatin, and vasopressin; (3) large proteins such as insulin, LH, and PTH that are produced by classic endocrine glands; (4) steroid hormones such as cortisol and estrogen that are synthesized from cholesterol-based precursors; and (5) vitamin derivatives such as retinoids (vitamin A) and vitamin D.

Feedback Regulation

The elucidation of negative feedback has had a profound impact on endocrinology. This principle holds that hormones have a particular set point that is controlled by downregulating stimulatory pathways when the set point is exceeded and upregulating stimulatory pathways when hormone levels fall below the set point. Probably every hormone is regulated in this manner, although the regulatory pathways might not be immediately evident for new hormones. These regulatory loops are well illustrated by the major hypothalamic-pituitary-hormone axes and include both stimulatory (e.g., TRH stimulates thyroid-stimulating hormone [TSH]; TSH stimulates T4/T3 production) and inhibitory components (e.g., T4/T3 suppress TRH and TSH) (Fig. 1.4). Feedback regulation also occurs for endocrine systems that do not involve the pituitary gland. For example, calcium feeds back to inhibit PTH, glucose inhibits insulin secretion, and leptin acts on hypothalamic

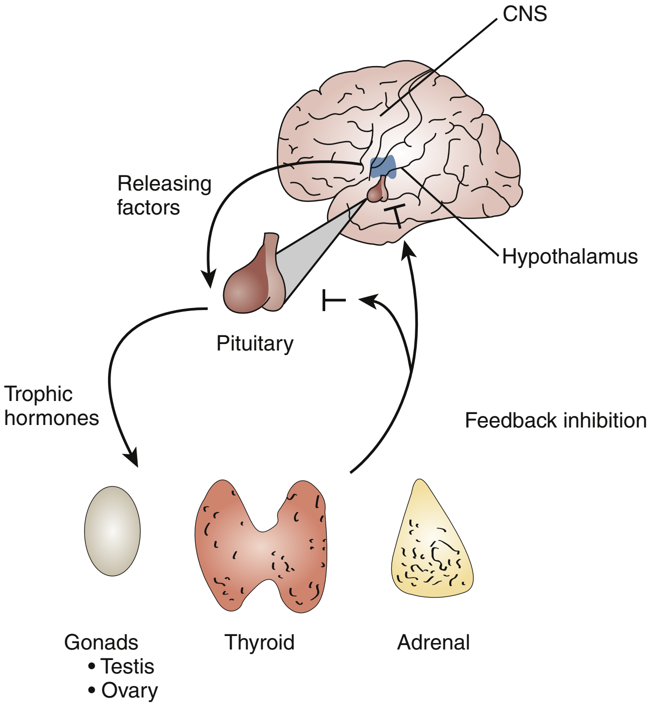

Fig. 1.4 Feedback regulation of the hypothalamic-pituitary axis. *CNS*, Central nervous system.

pathways to suppress appetite. Although the descriptions of these feedback mechanisms oversimplify the complex physiologic pathways that regulate hormone levels, they provide useful insight into endocrine testing paradigms. For example, hypothyroidism is characterized by elevated TSH, an appropriate physiologic response to deficient thyroid hormone levels. Dexamethasone suppression of the CRH/ACTH axis is used to diagnose Cushing disease, which is characterized by impaired negative feedback regulation. A deficient adrenal response to exogenous ACTH is used to document primary adrenal insufficiency.

KEY POINTS

- Feedback regulation is a powerful means to achieve homeostasis. It is also the foundation for important endocrine tests, such as the ACTH stimulation test or the dexamethasone suppression test.

Paracrine and Autocrine Regulation

Whereas feedback mechanisms control many classic endocrine pathways, local regulatory systems, often involving growth factors, play critical roles in all tissues (Fig. 1.5). Paracrine regulation refers to factors released by one cell that act on an adjacent cell in the same tissue. For example, somatostatin secretion by pancreatic islet delta cells inhibits insulin secretion from nearby β cells. The oocyte produces growth and differentiation factor–9, which acts on adjacent granulosa cells to stimulate the transition of primary follicles to secondary follicles. The anatomic relationships of cells have an important influence on paracrine regulation. Seminiferous tubules are exposed to a very high testosterone concentration from the interstitial Leydig cell compartment. On the other hand, the Sertoli cell product, androgen-binding protein, helps to retain high local testosterone concentrations. Activin exerts paracrine effects in the pituitary gland, where it stimulates FSH production. However, activin also exerts biologic activity in many other tissues, perhaps explaining why it is regulated locally and is neutralized by binding proteins such as follistatin. Autocrine regulation describes the action of a factor on the same cell from which it is produced. IGF-1 acts on many cells that produce it, including chondrocytes, breast epithelium, and gonadal cells. Intracrine regulation refers to effects within a cell. The term is not commonly used but captures the important concept that many signaling and enzymatic pathways are influenced by other pathways or by substrate or product concentrations. For example, 3-hydroxy-3-methylglutaryl coenzyme A reductase, the rate-limiting enzyme in cholesterol biosynthesis, is inhibited by the end product, cholesterol.

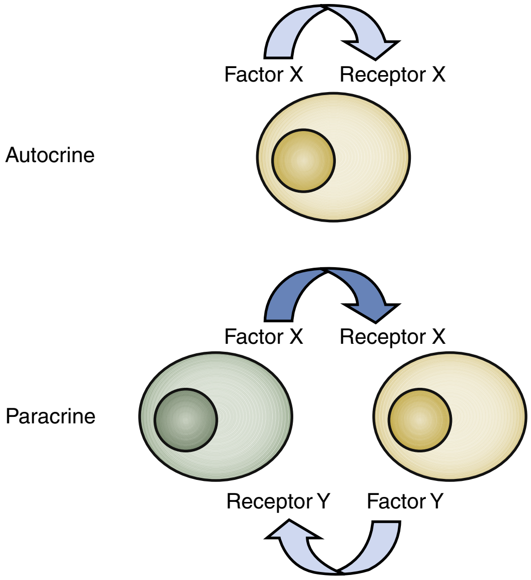

Fig. 1.5 Autocrine and paracrine regulation. Many growth factors act locally to regulate cell growth, differentiation, and function. Autocrine regulation describes the action of a factor that acts on the same cell, whereas paracrine regulation describes a circumstance in which the product of one cell acts on a different cell type.

KEY POINTS

- Paracrine and autocrine regulation allow growth factors and cytokines to act locally, minimizing systemic biological effects.

Hormonal Rhythms and Pulsatility

Hormonal rhythms are used to adapt to environmental changes, such as seasons of the year, the daily light-dark cycle, sleep, meals, and stress. In many species, reproduction is seasonal, presumably a mechanism to ensure survival of the offspring. In the extreme northern and southern hemispheres, calcium absorption and bone remodeling decline during winter, when vitamin D production is reduced. The human menstrual cycle is repeated on average every 28 days, reflecting the time required for follicular maturation and ovulation. In some species, estrus cycles are intimately linked to mating behavior induced by behavioral cues and the production of pheromones. Essentially all pituitary hormone rhythms are entrained to sleep and the circadian cycle, which in turn is dictated by sunlight exposure. The hypothalamic-pituitary-adrenal (HPA) axis, for example, exhibits characteristic peaks of ACTH and cortisol production before dawn and a nadir between late afternoon and midnight. Recognition of these rhythms is important for endocrine testing and treatment. Patients with Cushing syndrome exhibit inappropriately increased midnight cortisol levels. The HPA axis is more susceptible to suppression by glucocorticoids administered at night because they blunt the early morning rise of ACTH. Understanding this diurnal rhythm provides the basis for increased physiologic hormone replacement through the use of larger glucocorticoid doses in the morning than in the afternoon.

Although circadian rhythms were identified initially in the context of sleep cycles and hormonal rhythms, there is mounting evidence for circadian periodicity at the level of organs and individual cells.[23] For example, a number of genes expressed by hepatocytes, such as *REV-ERB,* exhibit rhythmic expression, thereby exerting epigenetic regulatory effects on metabolic pathways such as gluconeogenesis and lipid biosynthesis.

Many peptide hormones are secreted in discrete pulses, often reflecting regulation by the nervous system. For example, hypothalamic GnRH induces LH pulses once every 1 to 2 hours. Intermittent hypothalamic GnRH pulses are required to maintain pituitary gonadotrope sensitivity, whereas continuous GnRH exposure causes desensitization. This feature of gonadotropin regulation serves as the basis for using long-acting GnRH agonists to treat central precocious puberty or to decrease testosterone levels in the management of prostate cancer.

The pulsatile nature of hormone secretion and the rhythmic pattern of hormone production have important implications for the measurement of circulating hormone levels, as levels can change dramatically over several hours. For some hormones, integrated markers have been developed to circumvent hormonal fluctuations. For example, a 24-hour collection of urinary free cortisol integrates cortisol production throughout a diurnal cycle. IGF-1 provides a relatively stable biologic marker of GH action. Glycosylated hemoglobin is used as an index of long-term (weeks to months) circulating blood glucose, which is linked covalently to hemoglobin in a concentration-dependent manner.

KEY POINTS

- Virtually every hormonal system is linked directly or indirectly to circadian rhythms of sleep, light exposure, and feeding. These circadian rhythms not only influence physiologic responses but have practical implications for interpreting the measurements of many hormones.

Hormone Transport and Degradation

The level of a hormone is determined by its rate of secretion and its circulating half-life. After protein biosynthesis and precursor processing, peptide hormones are stored in secretory granules. These granules undergo progressive maturation and sequential translocation before arriving at the plasma membrane for imminent release into the circulation. The stimulus for hormone secretion is typically a releasing factor or neural signal that induces rapid changes in intracellular calcium concentration, which leads secretory granules to fuse with the plasma membrane and releases their contents into the extracellular environment and bloodstream. In contrast, steroid hormones usually diffuse into the circulation as they are synthesized. Thus, their secretion closely mirrors rates of synthesis. For example, ACTH and LH induce steroidogenesis by stimulating the activity of steroidogenic acute regulatory protein, which transports cholesterol into the mitochondrion. In parallel, ACTH and LH stimulate the production of other rate-limiting enzymes in the steroidogenic pathway, such as the cholesterol side-chain cleavage enzyme.

Hormone-binding proteins can affect volume of distribution, level of unbound or “free” hormone, and rates of hormone clearance. Most steroid hormones and many peptide hormones circulate in association with binding proteins. T4 and T3 bind to thyroxine-binding globulin (TBG), albumin, and thyroxine-binding prealbumin. Similarly, cortisol binds to cortisol-binding globulin, and androgens and estrogens bind to sex hormone–binding globulin (SHBG). IGF-1 and IGF-2 bind to multiple IGF-binding proteins. GH interacts with GH-binding protein, a circulating fragment of the GH receptor extracellular domain. Abnormal binding proteins can significantly alter total hormone concentrations but usually have little clinical consequence, as the regulatory feedback systems respond to unbound or “free” hormone levels. For example, TBG deficiency greatly reduces total thyroid hormone levels, but the free concentrations of T4 and T3 remain normal. Liver disease and medications can also influence binding protein levels (e.g., estrogen increases TBG). Nonetheless, these abnormalities can create diagnostic confusion, and some alterations (e.g., increased SHBG) may shift ratios of hormones (e.g., testosterone, estradiol) that bind with different affinities.

Knowledge of hormone half-life is important for achieving physiologic hormone replacement, as the frequency of dosing and the time required to reach steady state are determined by rates of hormone decay. T4, for example, has a half-life of about 7 days. Consequently, more than 1 month is required to reach a new steady state, and single daily doses are sufficient to achieve constant hormone levels. T3, in contrast, has a half-life of about 1 day. Its administration is associated with more dynamic serum levels, and it must be administered two to three times per day to generate more constant blood levels. Synthetic glucocorticoids vary widely in their half-lives. Analogues with a longer half-life (e.g., dexamethasone) are associated with greater suppression of the HPA axis. Most protein hormones (e.g., ACTH, GH, PRL, PTH, LH) have relatively short half-lives (<20 minutes), leading to sharp peaks of secretion and decay. These dynamic hormone fluctuations must be considered in analysis of hormone levels, which may vary widely over short time intervals and between patient visits. Although frequent hormone sampling can trace these pulses, this is not practical outside of a research setting. In some instances, clinicians elect to pool several samples to obtain a more representative hormone level. More often, clinicians recognize that the normal ranges are relatively wide, in part because of hormonal pulses. Rapid hormone decay is useful in certain clinical settings. Because PTH has a short half-life, intraoperative PTH can be used to confirm successful removal of a parathyroid adenoma. This is particularly valuable diagnostically when there is a possibility of multicentric disease or parathyroid hyperplasia, as occurs with multiple endocrine neoplasia or renal insufficiency.

KEY POINTS

- Precursor hormones provide another level of regulation of hormone bioavailability and action. For many hormones, such as POMC or preproglucagon, these precursors can generate multiple hormone products.

HORMONE ACTION THROUGH RECEPTORS

Hormone receptors can be divided broadly into membrane receptors and nuclear receptors. Membrane receptors primarily bind peptide hormones and small molecules that cannot traverse the plasma membrane (e.g., catecholamines, dopamine). Nuclear receptors bind small, lipid-soluble molecules that diffuse or are transported across the cell membrane (e.g., thyroid hormone, steroids, vitamin D). Hormones bind to both classes of receptors with specificity and high affinity. These characteristics are often described by Scatchard plots, which allow estimation of equilibrium dissociation constants and maximum binding (Fig. 1.6).

Binding affinity generally coincides with the concentration of circulating hormones and is typically in the subnanomolar range. Receptor occupancy at any given moment is a function of hormone

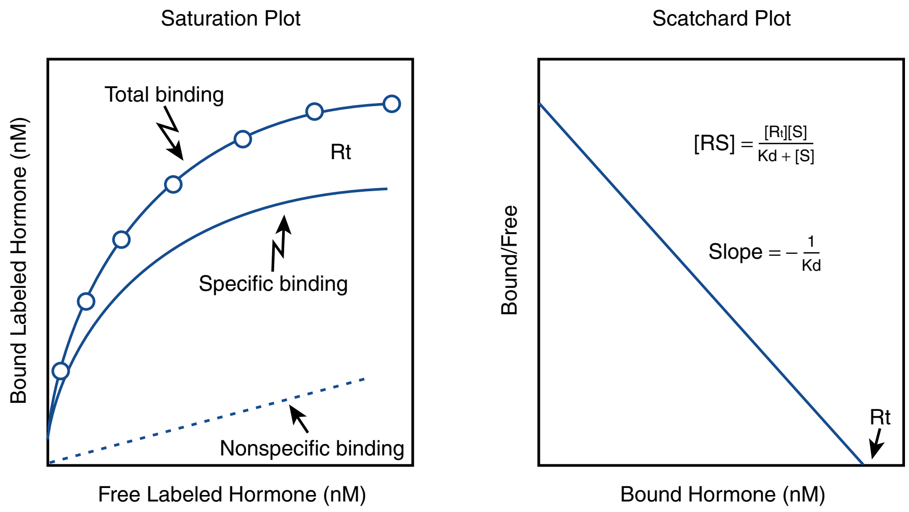

Fig. 1.6 **Plots of ligand–receptor interactions.** *Left panel,* Theoretical equilibrium saturation plot. As increasing amounts of labeled hormone are added, the amount of receptor-bound hormone increases until the binding sites are saturated (total binding). The addition of a large amount of unlabeled hormone allows determination of nonspecific or unsaturable binding. The hormone concentration at which half-maximal binding occurs provides a measure of binding affinity. *Right panel,* Theoretical Scatchard plot. The *x*-axis represents specific binding, and the *y*-axis denotes specific binding divided by free radioligand concentration. Maximal binding is estimated by the *x*-intercept, and the dissociation constant (K_d) is estimated as the negative reciprocal of the slope. *Rt,* receptor, total; *S,* substrate.

concentration and the receptor's affinity for the hormone. Receptor numbers vary greatly in different target tissues, providing one of the major determinants of specific cellular responses to circulating hormones. For example, ACTH receptors are located almost exclusively in the adrenal cortex, and FSH receptors are found predominantly in the gonads. In contrast, insulin and thyroid hormone receptors are widely distributed, reflecting the need for metabolic responses in all tissues. Tissue-specific knockouts of insulin receptors have revealed distinct metabolic actions of insulin in various tissues.[24] For example, deletion in muscle causes increased free fatty acids and adipose tissue, whereas insulin receptor deletion in adipose tissue reduces fat mass and enhances insulin sensitivity. Deletion of the receptor in pancreatic islet β cells impairs insulin secretion, apparently because of reduced islet cell mass.

KEY POINTS

- In general, peptide hormones interact with cell-surface membrane receptors, which in turn activate second messenger signaling pathways. Steroids, thyroid hormones, vitamin D, and retinoids are lipid-soluble and interact with intracellular nuclear receptors, which act predominantly by modulating gene transcription.

Membrane Receptors

Membrane receptors can be divided into several major groups (Fig. 1.7): (1) seven transmembrane domain G protein–coupled receptors (GPCRs), (2) tyrosine kinase receptors, (3) cytokine receptors, and (4) the transforming growth factor–β (TGF-β) family of serine kinase receptors. There are several hundred GPCRs.[25] They bind a broad array of hormones, including large proteins (e.g., TSH, PTH), small peptides (e.g., TRH, somatostatin), catecholamines (epinephrine, dopamine), and even minerals (e.g., calcium). These receptors possess seven transmembrane-spanning regions composed of hydrophobic α-helical domains that are connected by extracellular and intracellular loops. After the receptor binds a hormone, these transmembrane domains undergo conformational changes that alter interactions with intracellular G proteins. The G proteins provide a link to intracellular signaling pathways such as adenyl cyclase, phospholipase C, mitogen-activated protein kinases (MAPK), and others. G proteins form a heterotrimeric complex that is composed of various Gα and Gβ-γ subunits. The α subunit contains the guanine nucleotide–binding site and hydrolyzes guanosine triphosphate (GTP) to guanosine diphosphate (GDP). Gα

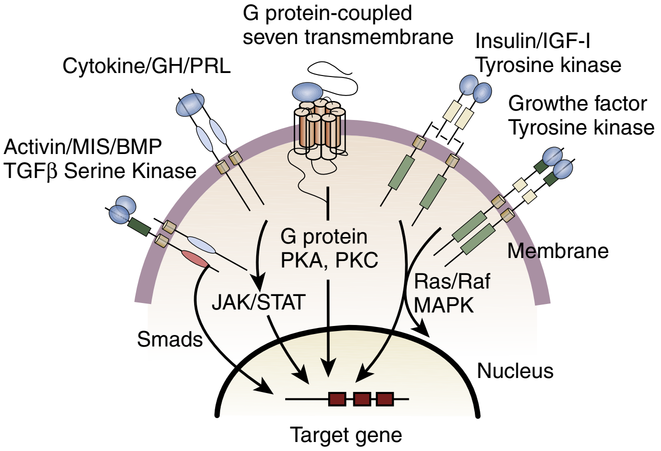

Fig. 1.7 **Membrane receptors.** Classes of membrane receptors can be defined on the basis of structural similarities and signaling pathways. The figure depicts major classes of membrane receptors, although these categories are somewhat arbitrary. Each of these receptor classes is described in a separate chapter. *BMP,* Bone morphogenetic protein; *GH*, growth hormone; *IGF*, insulin-like growth factor; *JAK,* Janus kinase; *MAPK,* mitogen-activated protein kinase; *MIS,* Mullerian inhibiting substance; *PKA,* protein kinase A; *PKC,* protein kinase C; *PRL,* prolactin; *STAT,* signal transduction and activators of transcription; *TGF,* transforming growth factor. (Modified with permission from *Harrison's principles of internal medicine.* 15th ed. New York: McGraw-Hill; 2001.)

is active when GTP is bound and inactive after hydrolysis to GDP. The Gβ-γ subunits modulate activity of the α subunit and mediate their own effector-signaling pathways. A variety of endocrinopathies result from G protein mutations or from mutations in receptors that modify their interactions with G proteins. For example, McCune–Albright syndrome is caused by somatic mutations in Gα that prevent GTP hydrolysis, thereby causing constitutive activation of the Gα signaling pathway. Selected mutations in the transmembrane domains of GPCRs can mimic hormone-induced conformational changes, leading to activation of G proteins independent of hormone binding. This type of mutation in the TSH receptor accounts for a significant fraction of solitary autonomously functioning thyroid nodules. Activating mutations in the LH receptor cause LH-independent precocious puberty in boys.

Tyrosine kinase receptors transmit signals for insulin and a variety of growth factors, such as IGF-1, epidermal growth factor, platelet-derived growth factor, and fibroblast growth factors. Ligand binding induces autophosphorylation, leading to interactions with intracellular adaptor proteins such as Shc and insulin receptor substrates. Depending on the receptor and adaptor complexes, one or more kinase pathways, including the Raf-Ras-MAPK and the Akt/protein kinase B pathways, are activated. The tyrosine kinase receptors play a prominent role in cell growth and differentiation, as well as in intermediary metabolism.

The GH and PRL receptors belong to the cytokine receptor family. Ligand binding induces receptor interactions with intracellular kinases such as the JAKs, which phosphorylate members of the STAT family, and other signaling pathways (Ras, PI3-K, MAPK). The activated STAT proteins translocate to the nucleus and stimulate expression of target genes.

The TGF-β receptor family mediates the actions of TGF-βs, activins, Müllerian inhibiting substance (MIS; also known as anti-Müllerian hormone), and bone morphogenic proteins. This receptor family consists of type I and II subunits, which undergo autophosphorylation after ligand binding. The phosphorylated receptors bind intracellular Smads (named for a fusion of terms for *Caenorhabditis elegans* sma + mammalian mad). Like the STAT proteins, the Smads serve a dual role of transducing the receptor signal and acting as transcription factors.

KEY POINTS

- Membrane receptors for hormones fall into four major groups that differ in their structures and signaling pathways: (1) seven transmembrane domain GPCRs, (2) tyrosine kinase receptors, (3) cytokine receptors, and (4) TGF-β family serine kinase receptors.

Nuclear Receptors

The nuclear receptor superfamily can be divided into receptors with known ligands (type I and II) and so-called orphan nuclear receptors, for which ligands have not been identified or might not exist.[26] Type I nuclear receptors include classic steroid receptors (e.g., glucocorticoid, estrogen, progesterone, androgen, mineralocorticoid) that bind to DNA as homodimers. Type II nuclear receptors bind to DNA as heterodimers, typically using the retinoid X receptor as a partner. Type II receptors bind a variety of molecules, including thyroid hormones, vitamin D, retinoic acid, and bile acids. Many orphan receptors bind DNA as monomers. Nuclear receptors have a highly conserved central zinc-finger DNA binding domain (Fig. 1.8). The carboxyterminal domain is more variable and includes a ligand-binding pocket, dimerization surfaces, and transcription-activating motifs. The aminoterminal domain varies greatly in length and in some receptors contains transcription-activating domains.

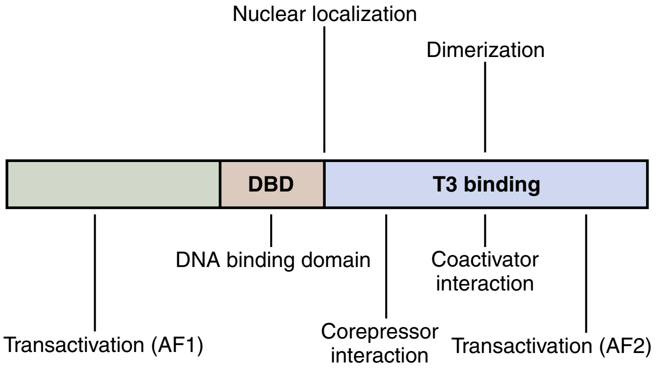

Fig. 1.8 Nuclear receptor structure. The central zinc-finger DNA binding domain is highly conserved among nuclear receptors. The carboxyterminus includes regions involved in ligand binding, transcriptional repression and activation, and dimerization. The aminoterminus is highly variable in length and, for some receptors, contains transcriptional regulatory sequences.

Nuclear receptors act primarily by altering rates of gene transcription, although there is growing evidence for interactions with other cellular signaling pathways, such as the MAPK pathway. Hormone binding induces conformational changes that induce receptor interactions with transcriptional cofactors. For type I receptors, ligand binding creates a bend in the extreme carboxyterminus (AF-2 domain) such that a hydrophobic cleft is created, providing a docking site for coactivators (e.g., steroid receptor coactivators). For type II receptors, hormone binding induces similar conformational changes. However, in the absence of hormone, corepressors are bound and silence gene transcription. Hormone binding induces the dissociation corepressors and the recruitment of coactivators (Fig. 1.9). Consequently, gene expression can shift from being silenced in the absence of hormone to being stimulated in the presence of hormone.

KEY POINTS

- Nuclear receptors mediate gene expression by recruiting an array of transcriptional corepressors or coactivators to alter rates of gene transcription or silencing.

ROLE OF THE CLINICAL ENDOCRINOLOGIST

Clinicians are often attracted to the field of endocrinology because it integrates physiology, biochemistry, and cell signaling with patient care. The fact that many endocrine disorders are amenable to cure or effective treatment also makes the practice of endocrinology especially satisfying.

As medicine becomes more specialized, physician roles are changing. Many general medicine inpatient services are now managed by hospitalists, who work in conjunction with primary care physicians and consultants. Inpatient length of stay continues to decrease, and this setting is now rarely used for extensive endocrine evaluation and testing. In fact, many endocrine pathways are perturbed by the stress associated with acute illness or hospitalization (e.g., sick euthyroid; false-positive dexamethasone suppression tests). These changes have resulted in a shift of an endocrinologist's activity to the outpatient setting.

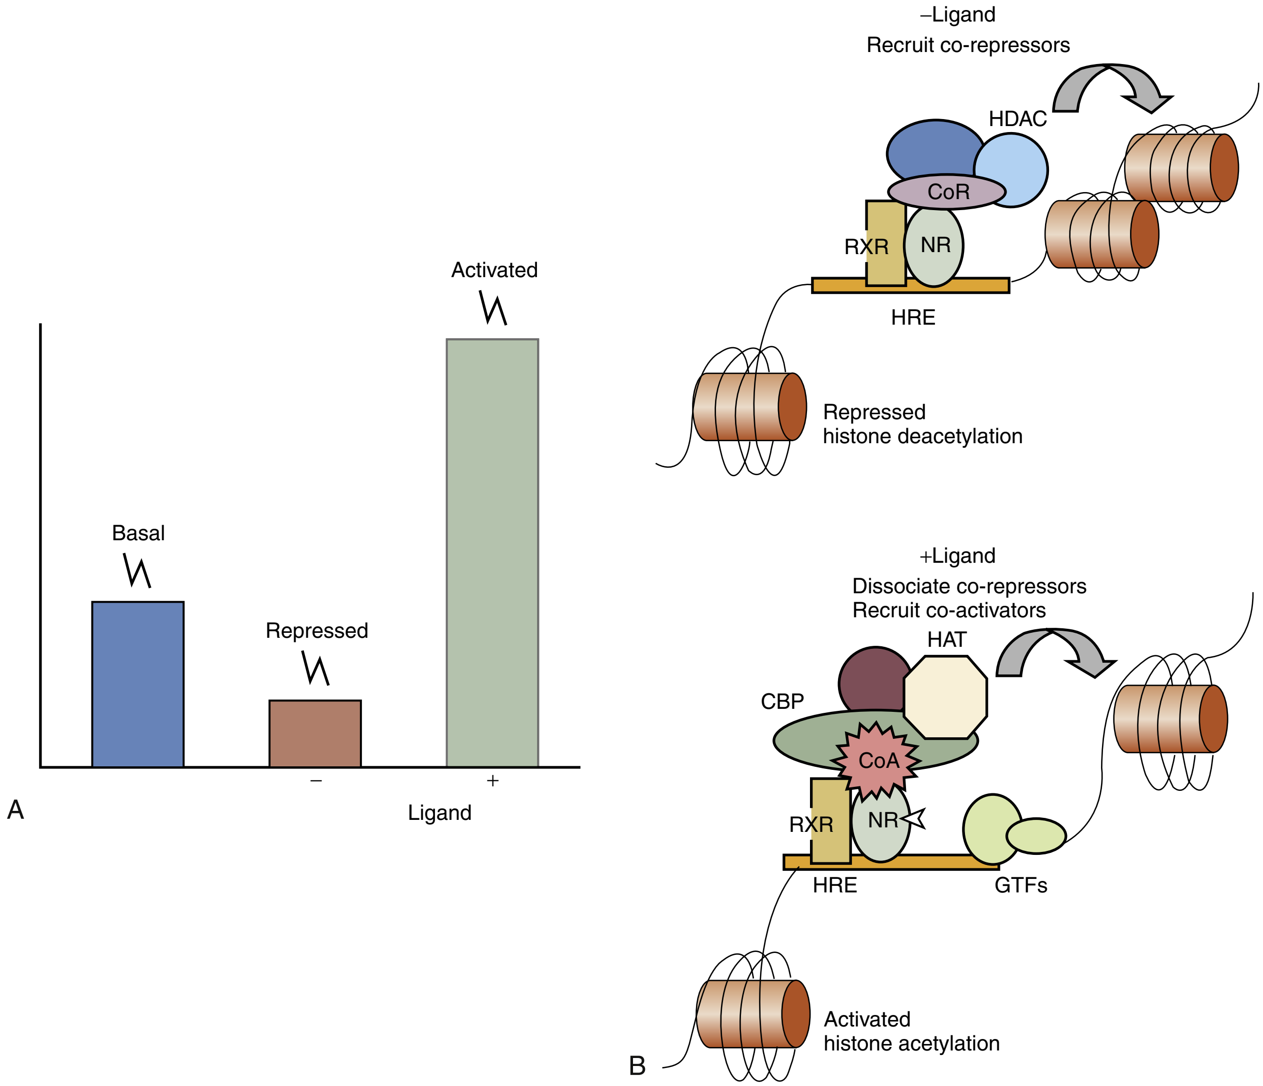

Fig. 1.9 Pathways of nuclear receptor transcriptional repression and activation. A, Nuclear receptors act primarily by altering rates of gene transcription. Many nuclear receptors, particularly type II receptors, cause transcriptional repression or silencing in the absence of ligand. After ligand binding, repression is relieved, and transcription is stimulated above the basal state. **B,** Although the exact mechanism of transcriptional repression or activation is variable, the model shown here illustrates ligand-induced relief of repression by corepressors (CoRs), followed by the recruitment of coactivators (CoAs). Many CoR complexes possess histone deacetylase activity, which is thought to induce gene silencing. CoA complexes possess histone acetylase activity, which induces changes in chromatin structure that facilitate the recruitment of additional transcriptional activators, which ultimately stimulate RNA polymerase. *CBP,* CREB-binding protein; *GTFs,* general transcription factors; *HAT,* histone acetyl transferase; *HDAC,* histone deacetylase; *HRE,* hormone response element; *NR,* nuclear receptor; *RXR,* retinoid X receptor.

Clinical endocrinologists serve three main roles: (1) to serve as consultants for patients who present with clinical endocrine conundrums that stretch the knowledge base and expertise of general internists or physicians in nonmedical specialties; (2) to provide specific short-term services for the treatment of endocrine disorders such as Graves disease, management of a thyroid nodule, or evaluation and treatment of hyperparathyroidism; and (3) to provide long-term management of challenging disorders such as brittle diabetes mellitus, congenital adrenal hyperplasia, or hypocalcemia. For many years, endocrinologists developed and performed specialized tests, including RIAs. In addition to performing appropriate stimulation or suppression protocols, special expertise was required to run and interpret these hormone assays. However, sensitive immunoradiometric assays, such as those for TSH, PTH, and most other hormones, are now commercially available. In some countries, these changes have influenced reimbursement, in that hormone testing generated revenue and compensated for other services, such as diabetes education. In the United States, endocrinologists are currently reimbursed primarily on the basis of evaluation and management coding, which takes into account the diagnosis and complexity of the evaluation. Endocrine procedures include thyroid aspiration biopsies, bone density measurements, and radioiodine treatment. However, wide institutional variation is seen in terms of who performs these procedures.

In addition to these classical roles, clinicians often make important contributions by recognizing new diseases or variants of old themes. For example, thyroid hormone resistance, lack of the GH receptor, and leptin deficiency states were identified in clinical practice. Often this role is played by the physician who sees patients and is involved in research: the clinical investigator.

Although practices vary considerably, the most common disorders seen by most endocrinologists are diabetes mellitus, thyroid disorders, metabolic bone disease, pituitary disorders, and reproductive abnormalities and infertility.[27] Pediatric endocrinologists also see a large number of patients with growth deficiency, pubertal delay, and a variety of inherited endocrine diseases such as congenital adrenal hyperplasia and Turner syndrome. Many academic centers have begun to structure multidisciplinary clinics for the management of diabetes mellitus, pituitary tumors, disorders of sex determination, and thyroid nodules.[28]

Increasingly, the clinical challenge is to identify endocrine disorders at their earliest stages before clinical manifestations are obvious. Terms such as *subclinical hypothyroidism, impaired glucose tolerance,* and *incidental adrenal* or *pituitary adenoma* have crept into our vocabulary and have changed our approach to patients. Similarly, endocrine disorders such as osteoporosis, hyperparathyroidism, hypertension, or hyperlipidemia rarely present with specific symptoms or signs. Because the clinical features of subclinical endocrine disorders are subtle or absent, laboratory testing takes on added importance as we attempt to diagnose more subtle forms of disease.

Available treatment options strongly influence the practice of endocrinology. Many new drugs have been discovered and approved during the past decade. Type 2 diabetes now can be treated by using drugs that influence insulin sensitivity (thiazolidinediones, metformin) and by administering agents that enhance insulin release (sulfonylureas, exenatide, repaglinide). Insulin derivatives with altered pharmacokinetics (lispro, aspart, glulisine, insulin glargine, detemir) facilitate intensive blood glucose control with a reduced risk for hypoglycemia. Bisphosphonates provide a novel mechanism for inhibiting osteoclast function and are widely used to treat osteoporosis and hypercalcemia. PTH analogs are being used to stimulate osteoblast function to enhance bone mass. Medical therapy for prolactinomas with dopamine agonists established a new paradigm for nonsurgical management of pituitary tumors. More recently, somatostatin analogues were developed, including depot formulations, for adjunctive or primary treatment of acromegaly. Pegvisomant is a novel GH analogue that blocks the GH receptor and is highly efficacious for reducing IGF-1 levels in patients with acromegaly. A variety of new formulations are available for delivering sex steroids. These include estrogen and testosterone patches. Testosterone gels and gum patches are also available. Building on the observation that tamoxifen exhibits mixed agonist/antagonist activity in various tissues, an active search is under way for additional selective estrogen receptor modulators (e.g., raloxifene) that exhibit unique profiles of estrogen action. It is expected that similar drugs might be identified for androgen, glucocorticoid, thyroid, and other nuclear receptors. Inhibitors of enzymes such as aromatase (anastrozole, letrozole) and 5α-reductase (finasteride) allow selective reduction of steroid levels. The potential for producing recombinant hormones has been fully realized, providing unlimited supplies of uncontaminated hormones or their derivatives. Examples of recombinant hormones in general use include insulin, GH, TSH, LH, and FSH. There is now great interest in the activities and clinical use of a variety of others, including leptin, GLP 1-37, YY 3-36, ghrelin, and others.

KEY POINTS

- Like most medical specialties, endocrinology is complex and requires highly specialized knowledge and experience. The effective consultant should gather information independently and decide whether to assume primary management of a patient if the clinical situation demands it, or to provide advice to the primary physician if the management is more straightforward.

MAJOR UNSOLVED PROBLEMS

Despite many impressive advances in endocrinology, a surprising number of fundamental problems remain incompletely solved. Although it is not possible to review all of these, it is provocative to identify a few, if only as a matter of perspective.

What is the basis of variability in normal ranges of hormones? The normal range for most hormones is remarkably broad. Testosterone, for example, varies between 300 and 1000 ng/dL, and total T4 ranges between 4 and 12 ng/dL. However, for any given individual, hormone levels are relatively constant, suggesting a defined set point. Some of this variability results from pulsatile or rhythmic hormone secretion. In some cases, differences in plasma-binding proteins account for variability. It seems likely that tissue responses, mediated by receptors and signaling pathways, also may define set points. From a practical perspective, the wide normal ranges create challenges for determining when subtle changes in hormone levels occur for a particular individual.

How should we optimally deliver hormone replacement? We currently have reasonable hormone replacements for most glandular deficiency syndromes. However, hormone replacement does not perfectly recapitulate normal physiology in any case. In type 1 diabetes, ideal insulin replacement would always maintain euglycemia without hypoglycemia. This challenge is underscored by the sometimes dramatic improvement in metabolic control after pancreatic islet transplantation. Thyroid hormone replacement, because of its relatively long half-life, approximates physiologic replacement, at least as assessed by TSH levels. Nonetheless, controversy about the need to replace T3 and T4 is ongoing. Glucocorticoid replacement is notoriously challenging, and patients often exhibit mild cushingoid features to avoid adrenal insufficiency. Ideally, we would use a physiologic marker, analogous to TSH, to assess adequate adrenal replacement. Similar issues exist for sex steroid replacement. Testosterone and estrogen replacement has been improved with the advent of patches and gels, but these delivery systems remain nonphysiologic. GH replacement in GH-deficient children rarely completely corrects height or even growth velocity. This might reflect relatively late diagnosis, or we might not have optimized hormone administration such that it mimics physiologic GH secretion or integrated actions with other hormones such as sex steroids. Many possible solutions to these challenges, including modified hormones and new formulations to alter absorption or pharmacokinetics, have been identified. In addition, careful clinical studies will be needed to correlate the physiologic effects of various hormone regimens.

How can osteoporosis be prevented? Currently, osteoporosis is identified after a fracture or on the basis of markedly reduced bone density. Treatment strategies can prevent further bone loss or can induce modest increases in bone mass. Clearly, it would be preferable to generate greater maximum bone mass early in life and to identify those who are at risk for accelerated bone loss.

What causes common autoimmune endocrinopathies such as type 1 diabetes mellitus, Hashimoto thyroiditis, Graves disease, and

Addison disease? Treatments are available for these disorders, but they are not directed at the underlying autoimmune process. If effective treatments could prevent, interrupt, or suppress the autoimmune process without causing significant side effects, the lifelong consequences of these disorders might be avoided. For autoimmune diseases associated with significant morbidity, such as type 1 diabetes, strategies directed toward immune tolerance should be considered, even if they are associated with moderate risk for complications or side effects.

What causes nodularity in endocrine glands? One or more nodules develop in the thyroid, pituitary, and adrenal glands in about 25% of patients when assessed at autopsy or with the use of sensitive techniques such as ultrasound or magnetic resonance imaging. The detection of "incidentalomas" is becoming commonplace as imaging methods are used more widely. Although these nodules are rarely malignant, they may produce excess hormones. Rarely, somatic mutations are found in nodules, and these may cause clonal expansion. More commonly, the nodules are polyclonal, and the causes are unknown. Understanding this process is likely to provide fundamental insight into neoplasia and create novel treatment approaches.

What regulates appetite and energy expenditure set points? The current obesity epidemic underscores the importance of understanding these metabolic processes to develop risk profiles and new treatments. The hypothalamic control of appetite is gradually being dissected, largely on the basis of mutations associated with severe, early-onset obesity (e.g., MC4R, leptin receptor)[29] and the identification of new appetite-regulatory hormones such as ghrelin. These pathways are potential targets for drugs that suppress appetite and/or increase energy expenditure.

As we look at the last 150 years of endocrinology and consider likely advances over the next decade, we have every reason to expect the pace of discovery to accelerate. Many advances have been driven by new technologies such as RIAs, recombinant DNA technology, and imaging. Current technology focuses on genomics, proteomics, metabolomics, nanotechnology, epigenetics, bioinformatics, and the use of computerized information systems in clinical practice. As scientists and clinicians, we will harness these and other technologies to tackle the many unanswered questions that remain in endocrinology.

KEY POINTS

- The field of endocrinology is dynamic and changes continuously, emphasizing the importance of lifelong learning, rigorous literature review, and participation in seminars and conferences to keep up with the latest advances.

INTRODUCTION AND BRIEF HISTORY OF ENDOCRINE ASSAYS

KEY POINTS

- The invention of the radioimmunoassay was a seminal event in the evolution of modern clinical and experimental endocrinology.
- Nonisotopic immunoassays have better safety and throughput than radioactive assays.
- Structural assays (e.g., chromatography and mass spectrometry) represent a major diagnostic advance, particularly in the measurement of small molecules such as steroids.

The accurate measurement of hormones in body fluids is critical to the practice of clinical endocrinology and is necessary for proper diagnosis and monitoring of treatment. Clinicians depend on the reliability, sensitivity, specificity, and reproducibility of the laboratory results they receive. This requires a symbiotic partnership between the clinical endocrinologist and the clinical laboratory.

This chapter will provide practical explanations for clinical endocrinologists to understand the tests that they order and will avoid greatly detailed explorations of method techniques. For more detailed technical descriptions of individual endocrine assays, we recommend the excellent chapter by Sluss and Hayes.[1]

Radioimmunoassay

The seminal event in the genesis of the modern hormone assay was the groundbreaking work of Yalow and Berson in the development of the radioimmunoassay (RIA), for which Dr. Yalow received the Nobel Prize.[2] (Dr. Berson was deceased when this Nobel Prize was awarded in 1977.) Before the development of the RIA, hormone measurements were primarily performed using bioassays and chemical-based assays.[3] These assays were very labor-intensive and slow, required significant technical expertise, and were notoriously unreliable. Examples of early cellular bioassays include the use of ovarian ascorbic acid depletion for the measurement of serum luteinizing hormone (LH)[4] and adrenal ascorbic acid depletion for plasma adrenocorticotropic hormone (ACTH).[5,6] Another example is the plasma vasopressin bioassay, which measured antidiuresis in the water-loaded rat.[7,8] There were no reliable bioassays for steroid and thyroid hormones, so chemical methods such as the fluorometric assay were developed.[9]

The development of the RIA for peptides in the late 1950s liberated us from the need for bioassays and chemical assays; this method was novel in its reliance on the use of antibodies for the specific detection of an analyte. The history of the development of the plasma insulin RIA has been extensively documented and provides a good example of one type of RIA design.[10,11] The basic concept was the incubation of fixed concentrations of radiolabeled human insulin and a polyclonal antibody specific for insulin with increasing concentrations of unlabeled insulin. The unlabeled insulin and radiolabeled insulin compete for the same binding site on the antibody, giving a classic inverse hyperbolic curve after separation of the bound and free radiolabeled insulin and the measurement of the bound to free fraction ratio (Fig. 2.1). Thus, this is called a competitive binding assay, where the final analyte concentration is inversely proportional to the signal produced by the assay. An RIA's sensitivity and specificity depended on the quality of the antibody used and the availability of a pure hormone standard. Also, the serum, plasma, or urine sample often required a tedious and time-consuming extraction step to avoid matrix effects, improve sensitivity, and eliminate as many interfering substances as possible.

Another example of the revolutionary nature of this method was the development of the RIA for measurement of plasma ACTH[12,13] (Fig. 2.1). Notice that the "sweet spot" of the assay ranged from approximately 5 to 80 pg/mL and encompassed the results from a "normal subject" when accounting for the 5-fold dilution of plasma. Also note the ability to differentiate the diurnal nadir and peak in a normal subject and the identification of the very high ACTH result in a patient with primary adrenal insufficiency (Addison disease). The plasma ACTH RIA was the state of the art until it was replaced by the noncompetitive two-site "sandwich" immunometric assay.[14]

RIA methods are reliant upon the production of specific antibodies, taking advantage of amino acid sequence and structural differences in peptides from different species to allow the production of specific antibodies by immunizing animals. However, adapting RIA methods to the measurement of human steroids was challenging, as steroid hormones are

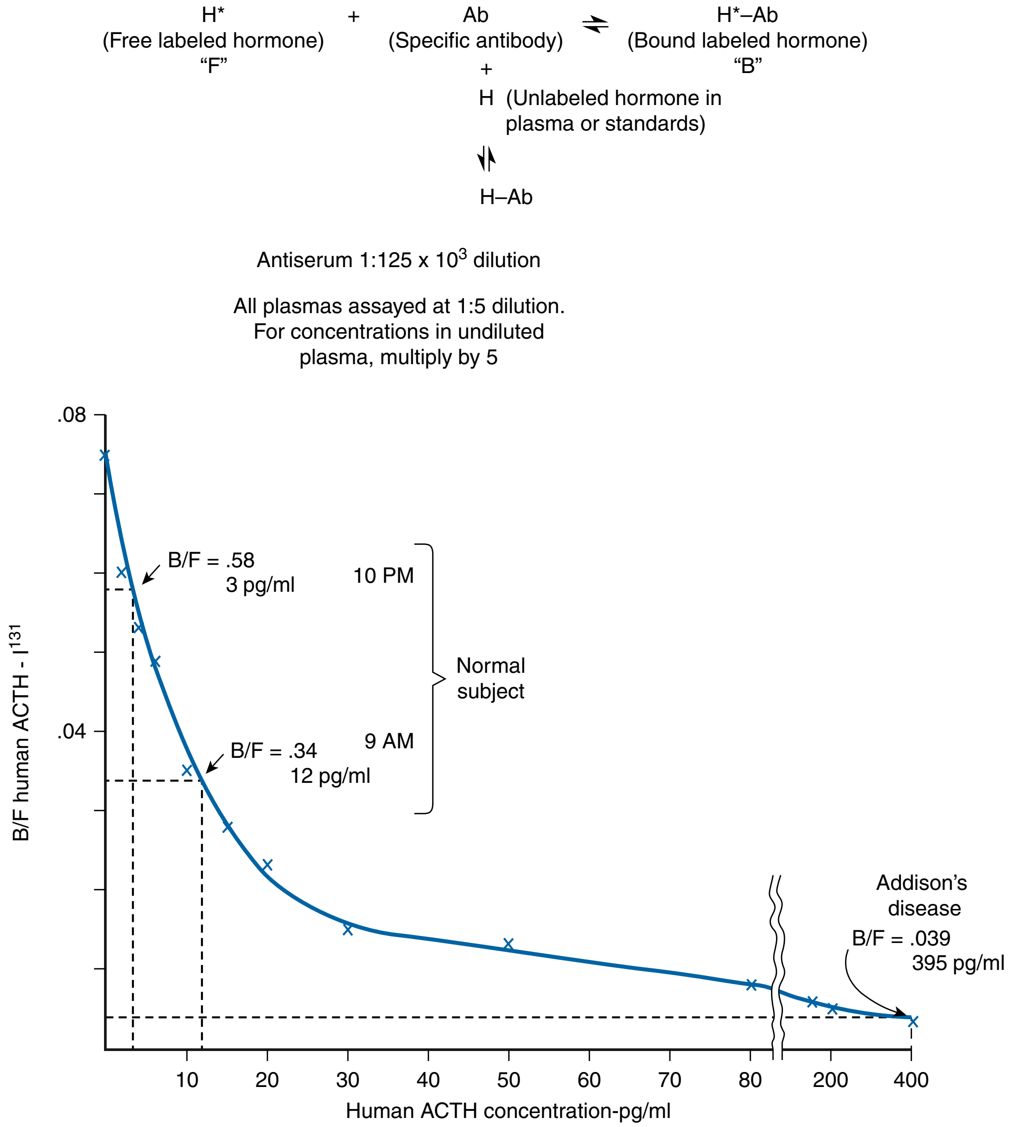

Fig. 2.1 Principle of the competitive binding radioimmunoassay. An unlabeled hormone competes with labeled hormone for binding to a specific antibody. The more unlabeled hormone in the sample, the less labeled hormone is bound to the antibody. Separation and measurement of the bound (B) and free (F) fractions generates a standard curve from which the concentration of the hormone can be interpolated. *ACTH*, Adrenocorticotropic hormone. (Modified from Berson SA, Yalow RS. General principles of radioimmunoassay. *Clin Chim Acta*. 1968;22:51–69.)

not immunogenic by themselves. To develop useful antibodies for steroid hormone assays, the steroid had to be conjugated to immunogenic substances like bovine serum albumin.[15,16] Whereas noncompetitive immunoassays have supplanted competitive binding assays for larger peptides, competitive binding assays based on the original design of the RIA are still used for smaller substances such as steroids and thyroid hormones.

Nonisotopic Immunoassays

There were several reasons for the desire to use methods other than radioisotopes to detect hormone binding. First, there are obvious regulatory and safety issues. In addition, the gamma-emitting isotopes of iodine used for many RIAs (e.g., ^{125}I) have a relatively short half-life, thus limiting their shelf life. The development of alternated methods to label antigen, and subsequently antibody, was obviously needed. The development of the enzyme immunoassay (EIA) and enzyme-linked immunosorbent assay (ELISA) was a major advance in this regard.[16,17] Immobilization of antibody or antigen in a well or tube format also facilitated simple separation of bound from free components, if necessary. The basic method of generating a measurable signal in these assays is via the conjugation of antigen or antibody to an enzyme rather than a radioisotope. Subsequent addition of the appropriate chemicals produces a detectible color change that is proportional (either directly or indirectly, based on the assay design) to the amount of binding. This color change is easily measured with a relatively inexpensive spectrophotometer (i.e., “plate reader”) available in virtually any laboratory. Since then, other methods such as chemiluminescent and fluorometric labels have been developed that improve automation, sensitivity, throughput, and costs, but the basic concepts of the methods are the same.

Monoclonal Antibodies

The quality of an immunoassay is dependent upon the generation of sufficient antibody with high sensitivity and specificity for the antigen (hormone) in question. Polyclonal animal-generated antibodies were the state of the art until the development of monoclonal antibodies from mouse hybridoma cells, for which Millstein and Kohler received the Nobel Prize in 1984.[18] This method allows the generation of large quantities of highly specific antibodies and is currently used for many clinical assays.

Structural Assays

Almost simultaneous with the development of immunoassays was the development of structural methods such as ultraviolet detection and mass spectrometry that measures the ratio of mass to charge of ions.[19-21] The ion trap method of mass spectrometry was developed by Dehmelt and Paul, who received the Nobel Prize in Physics in 1989. Additional advances included the electrospray ionization method developed by Fenn and the soft laser desorption method developed by Tanaka, who shared the Nobel Prize in Chemistry in 2002. Since then, the development of tandem mass spectrometry (MS/MS) has revolutionized the use of this method in clinical laboratories.[22,23] Of course, none of these methods would be useful clinically without the development of high-performance liquid chromatography (HPLC, or LC) in the 1940s through the 1970s.[24,25] The LC-MS/MS method has replaced the slower and more challenging gas chromatography–MS in most clinical applications.[26]

Preanalytic Methods and Harmonization of Assays

Two additional matters merit a brief discussion. The first is the concept of *preanalytic error*.[27] The results generated in the clinical laboratory are only as good as the samples that are provided for analysis. Improper sample tube type (e.g., serum vs. ethylenediaminetetraacetic acid (EDTA) plasma), careless sample handling and processing, and lack of attention to patient preparation (e.g., discontinuation of interfering drugs such as biotin, fasting state, and assuring the correct sampling time) can negate a result generated by even the best analytic method. Any root cause analysis of a problematic result requires assessment of potential preanalytic errors in addition to analytic imprecision.

Secondly, it is important to realize that very few hormone assays have undergone harmonization or standardization, or require accuracy-based quality assessment schemes.[28] This is a costly and time-consuming process and requires cooperation of governmental accrediting bodies and reagent manufacturers.[29,30] Many clinicians are familiar with the variability of results they receive for the same patient from different laboratories using different methods.[31-33] Importantly, this fact reinforces the need to use laboratory-specific reference intervals. When confronted with an unexpected or unexplainable laboratory result, one can confirm that the sample was drawn and processed properly, and, if necessary, repeat the test or refer the sample to an alternate laboratory.

OVERVIEW OF GENERAL CONCEPTS

KEY POINTS

- Preanalytic variables such as patient preparation, sample collection, and sample processing are critical to generate reliable hormone measurements.
- Understanding that reference intervals are specific to the method and laboratory is essential for the proper interpretation of test results.
- Most assays are susceptible to interferences that must be considered when interpreting laboratory results.

Whereas laboratory testing represents a relatively small portion of overall healthcare expenditure (~5%), laboratory test results contribute to an estimated 70% of overall critical decision-making, including diagnosis, medication management, and admitting/discharging decisions.[34] The “brain-to-brain loop,” first published by Lundberg in 1981,[35] identified the numerous steps that occur between clinicians ordering a test and their interpretation and eventual action on a result: collection, identification, transportation, preparation, analysis, and reporting. Appreciation of issues surrounding the integrity of the sample itself, the analytical and clinical performance of a laboratory measurement, comparison of patient results to reference values, and known assay interferences are all critical to interpreting the final result.

Preanalytic Variables

Patient Preparation: Any test result is only as good as the sample used for the measurement. This simple, yet often overlooked, fact cannot be overstated. A patient’s posture, diet, medications and supplements, fasting status, stress, race, gender, activity level, and hydration status, as well as the sampling time and collection method, can all have physiologic effects on certain analytes or may interfere with their analytic measurement.

Stress is known to increase ACTH, cortisol, and catecholamine concentrations.[36-38] Exercise before sample collection can increase the concentrations of hormones such as prolactin, growth hormone, cortisol, glucagon, and catecholamines.[37,39] Moving from recumbent to upright positioning decreases overall plasma volume and concentrates protein as fluid moves toward the lower extremities.[40] This hemoconcentration affects protein-bound analytes such as calcium and sex steroids.[40] Food intake or fasting status naturally affects blood glucose and lipid concentrations, but also gastrin, insulin, renin, aldosterone, and cortisol concentrations.[41] These situations should be limited or noted during the sample collection process to aid eventual interpretation of results.

Timing of sample collection is particularly critical for endocrine analytes. A common example is measuring analytes associated with female reproduction and the menstrual cycle. Many hormones also have a daily rhythm. It is critical that clinicians be very specific about timing when placing a laboratory test order and educating the patient about the importance of sampling at the correct time. A rule of thumb is that the sample should be obtained at the circadian peak if a hormone deficiency is suspected and at the circadian nadir if hormone excess is suspected. For example, evaluation of male hypogonadism should measure testosterone in a morning blood sample (circadian peak), whereas salivary cortisol for the diagnosis of Cushing syndrome must be performed on samples collected at bedtime (circadian nadir).[42-44] Although the time of collection should be reported along with each laboratory result, making this problem obvious in retrospect, it saves a lot of time and confusion if the sample is collected at the correct time in the first place.

Avoiding errors in patient identification is central to the patient safety mission of most institutions, because of the potential negative outcomes. Updated sample collection protocols and electronic solutions are examples of methods used to limit these errors.

Sample Type and Collection: The sample types that can be used for laboratory measurements are almost limitless. Each sample type has limitations, challenges in collection and processing, and certain clinical benefits.

Serum is the aqueous portion of whole blood remaining after clot formation, whereas plasma is the aqueous portion remaining when an anticoagulated blood sample is separated into aqueous and cellular portions. Whole-blood samples are exposed to anticoagulant but not separated. Plasma and serum differ in their composition; for example, serum does not contain fibrinogen (consumed by clot formation) and has slightly higher potassium concentrations (released by platelets during clot formation) than plasma.

Urine samples may be collected at a single time (random "spot" urine) or over a full 24-hour period to normalize for variation in secretion and clearance over time.[45] For 24-hour collections, it is best to measure urinary creatinine simultaneously to verify an adequate collection and control for variations in urine flow rates.[46,47]

Saliva or oral fluid is considered an ultrafiltrate of the plasma and represents the "free" or unbound portion of some analytes. The most common use of saliva samples is for the measurement of cortisol in the diagnosis of Cushing syndrome (late-night salivary cortisol) and during cosyntropin stimulation testing in patients with poor venous access.[38,48] The advantages are particularly notable for cortisol measurements; the noninvasive sampling of saliva and the ability to perform sampling at home in a low-stress environment reduce the chance of artificially elevated cortisol values because of unfamiliar surroundings and overall stress.[49] In fact, a new, noninvasive cosyntropin stimulation test has been developed with nasal ACTH administration and salivary cortisol sampling.[50] The two main potential problems with home saliva sampling are the inability to verify that the sample was obtained at the correct time and assurance that the sample has not been contaminated (e.g., with topical steroids, blood).[51]

For blood samples, different tubes and collection devices are available, and their use depends on factors such as the analyte(s) and sample type(s) to be measured, how quickly a sample must be tested, and the laboratory methods that will be used. Most frequently encountered are blood collection tubes that contain additives to either accelerate (serum) or prevent (plasma) clot formation; however, special tubes may also be required for uses such as preserving specimens for cell counts, trace metals or toxicological assessments, or blood cultures. Additives and preservatives used in some collection tubes may interfere with laboratory measurements (e.g., lithium heparin additive will interfere with lithium measurements, and potassium EDTA chelates calcium and magnesium). Therefore, tubes are collected in a specific order to avoid contamination of additives and preservatives from one tube to the next.

Analytical Parameters

Reliable test results start with reliable methods. The clinician's dependence on accurate test results dictates the need for stringent evaluation of a method before its use. The eventual clinical application of a test result, along with the robustness of the analytical method, help drive the evaluation and acceptance criteria used. Most frequently encountered laboratory tests are either commercially developed or developed by an individual laboratory (often referred to as a Laboratory-Developed Test). Each requires review of different criteria to determine acceptable performance. Metrics associated with both analytical and clinical performance are reviewed and compared against the amount of error that would be considered clinically acceptable.

Analytical performance metrics include imprecision, accuracy, sensitivity, and specificity. Imprecision refers to the reproducibility of an individual result. It estimates the random error, or dispersion around the mean, associated with the analytic error of the method. In other words, if you were to test the same sample multiple times, what amount of variation would you expect? The standard deviation (SD) and coefficient of variation associated with those measurements provide a quantitative measure of imprecision. Accuracy describes the difference between the "true" value and that obtained by your method; that difference describes the bias of the testing method. Any existing bias between your method and whatever is established as "truth" (e.g., a gold standard or reference method) can be determined by comparison, recovery, or interference studies. Figure 2.2 illustrates imprecision and accuracy in terms of a bullseye, with the center of the bullseye representing "truth." Data points that are close to each other are considered precise, and those that are close to the center of the bullseye are considered accurate. The best clinical laboratory tests are both precise and accurate.

Analytical sensitivity studies determine the lower limit of detection for a particular assay, whereas analytical specificity evaluates whether similar compounds may cross-react with your method. These measures should not be confused with clinical sensitivity and specificity, described later.

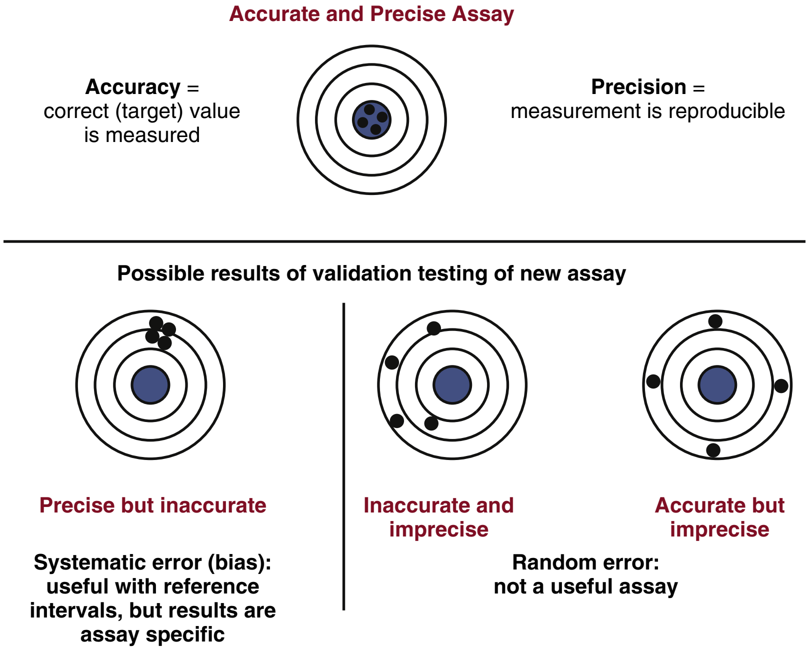
Clinical Parameters

The clinical diagnostic accuracy of a laboratory test requires comparison of it to an index, or reference, method of diagnosis; this may be another well-defined laboratory test or a more direct measure of disease, such as biopsy. Comparisons between the index test and the test in question reveal "true" (index and testing methods match) and "false" (index and testing methods do not agree) positive and negative results. Mathematical calculation of those individual values provides the test's clinical sensitivity (ability to accurately provide a positive result in the presence of disease) and clinical specificity (ability to accurately provide a negative result in the absence of disease). When the prevalence of a disease is factored in, positive and negative predictive values can also be calculated, which describe the overall reliability of a positive or negative value.

Reference Intervals

Reference intervals are defined as the range of values observed in a reference population for the analyte of interest. Most laboratory results are accompanied by analyte- and laboratory- or method-specific reference intervals which allow for comparison of the patient's result to the expected results obtained from a similar population. Intervals are typically generated from a population of "healthy" individuals whose age, sex, race, and/or ethnicity represent the population of interest.

Identifying an appropriate reference population is complex and central to defining an appropriate reference interval. Defining "healthy" in respect to the analyte you are measuring and obtaining samples from "healthy" patients can be particularly challenging. Strictly defined inclusion and exclusion criteria are needed for



Accurate and Precise Assay
Accuracy = correct (target) value is measured
Precision = measurement is reproducible
Possible results of validation testing of new assay
Precise but inaccurate
Inaccurate and imprecise
Accurate but imprecise
Systematic error (bias): useful with reference intervals, but results are assay specific
Random error: not a useful assay

Fig. 2.2 Assay accuracy and precision are related parameters that are used to assess the quality and reproducibility of an assay. (From Sluss PM, Hayes FJ. Laboratory techniques for recognition of endocrine disorders. In: Melmed SA, Goldfine, RJ, Koenig, AB, et al., eds. *Williams Textbook Of Endocrinology.* 14th ed. Philadelphia, Elsevier; 2020:62–90.e66.)

the reference population to ensure the resulting values provide an accurate picture of the analyte of interest. An example of the need for a well-defined reference population is the reference interval for thyroid-stimulating hormone (TSH). If not screened carefully, the reference population may contain individuals with subclinical thyroid disease.[52-54] Established intervals from those individuals may thus be skewed, resulting in possible misdiagnosis of clinical patients once implemented.

For certain subpopulations, identifying a true reference population is challenging at best and impossible at worst. Examples include scenarios where samples from healthy individuals are extremely limited in availability or volume, such as pediatric populations. Samples are rarely taken from healthy children; if samples are obtained, it is usually as part of a clinical investigation, or the child is ill. That makes it very difficult to obtain samples to determine pediatric reference intervals. National and international efforts have attempted to address this gap by establishing well-characterized repositories of samples from healthy children and using these to develop subsets of pediatric reference intervals.[55-58] Another extremely challenging example relevant to endocrinology is reference intervals for dynamic (suppression or stimulation) testing. These investigations are performed in individuals suspected of having disease. To replicate that scenario for the purposes of a reference population, suppressing or stimulating substances would need to be administered to healthy individuals which would not routinely be approved by modern institutional research review boards. Another example is reference intervals for analytes measured in body fluids or extracted tissue. These sample types are associated with pathology and would not be obtained from healthy individuals to measure reference intervals.

Reference intervals are often partitioned into groups that have statistically distinct values. Examples include estradiol and testosterone in adult men versus women or bone markers and creatinine in children versus adults. In endocrinology, many analytes are partitioned by sex, age, menstrual cycle phase, trimester of pregnancy, Tanner stage in children, etc. There are differences between races for measures such as hemoglobin A1c, with Black Americans having significantly higher values than non–Black Americans.[59] Establishing reference intervals *de novo* requires many healthy individuals, so the need for multiple partitions rapidly increases the number of volunteers or samples needed.

Samples are often obtained from laboratory personnel for reference interval determinations. This approach does have limitations. One example is determining reference intervals for analytes that are dependent upon ambulatory status or stress such as plasma catecholamines. Slight increases in plasma catecholamine concentrations are a common finding in patients without pheochromocytoma.[60] This is likely resulting from the stress of a having a blood sample collected from a patient compared to a healthy volunteer used to having routine blood draws performed.

There are a few analytes (e.g., hemoglobin A1c, cholesterol, 25-hydroxyvitamin D) for which the laboratory provides a "desired" or "optimal" level rather than a reference interval. These desired levels are typically opinions of experts, based on clinical and actuarial data, and can lead to controversy.[61,62]

A common mistake is confusing the terms "reference interval" and "normal range." There really is no such thing as a normal range; reference intervals should be viewed as a guidance, because they rarely distinguish between health and disease on their own. Consider a patient with Cushing disease in whom a plasma ACTH concentration within the reference interval is clearly not "normal." The preferred term in this case is "inappropriately not suppressed" for the degree of hypercortisolism. Another example is a serum TSH concentration within the reference interval in a patient with hypothyroidism, that is, "inappropriately not increased" for the degree of hypothyroidism that can lead to the diagnosis of secondary hypothyroidism (i.e., hypopituitarism). These concepts are challenging to explain to nonexperts. Unfortunately, the archaic term “normal range” is ingrained in clinicians.

Statistics applied to the data generated from the reference populations define the lower and upper limits of these intervals. Parametric statistics are used when the data follow a Gaussian (normally distributed or bell-shaped) curve, whereas nonparametric statistics are not limited by the data’s distribution and rank the values from lowest to highest. Because many biological analytes are skewed (non-Gaussian) in their distribution, guidelines for determining reference intervals recommend the use of nonparametric statistics.[63] Establishing a reference interval *de novo* also requires a considerable number of individuals. Statistical significance requires a minimum of 120 individuals per partition to establish a new reference interval; a smaller number is required if a laboratory is verifying an existing interval.[63] Reference intervals are frequently based on the central 95% of measured values (mean ±2 SD for normally distributed analytes, 2.5th to 97.5th percentiles for nonnormally distributed analytes), which naturally indicates that 5% of values obtained from a healthy population would not be represented in a typical reference interval. All laboratory methods have imprecision associated with their measurements; thus, clinical results that are very close to the reported reference limits should be interpreted within the context of the clinical situation, as these reference intervals are not absolute cutoffs.

General Interferences

Each assay method is susceptible to different types of interference, which will be discussed for individual methods later in this chapter. However, there are some general concepts that are important.

Patients may be taking a medication or supplement that interferes with a particular laboratory test. This could be an analog of a hormone, which would falsely elevate the measurement of that hormone. A classic example is prednisone (prednisolone) cross-reactivity in serum total cortisol immunoassays.[64] This is typically not a problem in current structural assays for cortisol (i.e., LC-MS/MS) because of the assay design. There are also drugs that can falsely decrease a hormone result. A relatively common example is related to the ACTH stimulation test used to evaluate the cortisol response in a patient suspected of having adrenal insufficiency. Baseline assessment of the patient’s plasma ACTH concentration is needed to determine their ability to produce ACTH.[38] However, incorrectly collecting the sample after injecting the standard 250-μg cosyntropin/synacthen ($ACTH_{1-24}$) dose occurs fairly frequently, particularly in hospitalized patients. Because plasma $ACTH_{1-24}$ concentrations are enormously high after injection, collecting the sample after cosyntropin administration paradoxically leads to an abnormally low plasma $ACTH_{1-39}$ result. This is because of the design of the noncompetitive two-antibody sandwich assay used to measure ACTH concentrations (discussed later in this chapter).[65] This could result in the erroneous diagnosis of hypopituitarism (suppressed plasma ACTH) rather than primary adrenal insufficiency (increased plasma ACTH). A third, now well-known, interfering substance biotin, which is used in mega-doses for cosmetic reasons or as a treatment for multiple sclerosis[66,67] or other disorders.[68,69] Biotin can either falsely decrease or increase the hormone result in methods using biotin-streptavidin conjugation; the effect is dependent upon the assay design.[70] These interferences will be discussed where appropriate as this chapter proceeds.

Another common problem occurs in the measurement of serum total thyroid and steroid hormones, which normally circulate in a large part bound to plasma proteins. Obviously, an increase in binding proteins (e.g., increase in corticosteroid-binding globulin [CBG] and thyroxine-binding globulin [TBG] by estrogen therapy or contraceptives) or decrease in binding proteins (e.g., during critical illness, nephrotic syndrome) can confuse the total hormone measurement.[36,71,72] This will be discussed in the section on free hormones later.

Summary

A laboratory test is only as reliable as the sample on which it was performed. Similarly, interpreting a result requires a well-characterized and reliable reference interval. The possibility of interferences with laboratory measurements should be considered when results are incongruous with the clinical scenario. Practical approaches to these situations include repeating the sample collection with close attention to preanalytic variables or, depending on the analyte, requesting measurement by a different method, if possible. These clinical decisions should be made in consultation with a clinical laboratory director familiar with the testing that was performed.

COMPETITIVE BINDING ASSAYS

KEY POINTS

- Competitive binding assays typically use an antibody to bind the unknown hormone of interest in competition with a labeled form of the hormone.
- Simplicity and high-throughput automation are the main advantages of the competitive binding assay.
- Disadvantages include a limited analytic range and cross-reactivity to and interference by other factors, homologous hormones, and metabolites.

The competitive binding assay (typically performed by immunoassay) revolutionized clinical endocrinology and was briefly described in Figure 2.1. The key to the performance of this assay is the use of a moiety that has specific binding sites for the analyte to be measured. Typically, this is a specific polyclonal or, subsequently, monoclonal antibody (hence the term “*immuno*assay”). However, there are other less common approaches such as the use of corticosteroid-binding globulin (CBG; transcortin) as the *in vitro* binding moiety.[73] The use of a single antibody dictates the need for a small target; epitope size, overall confirmation, and folding of the target must allow for binding by a single antibody.

Principle

Figure 2.3 depicts the general design of the competitive binding assay. The (unlabeled) patient sample is mixed with a constant and limited amount of labeled analyte (antigen); analyte-specific antibody is added, and the unlabeled and labeled analytes compete for binding to the same (limited) antibody binding sites. The amount of labeled analyte bound to the antibody is inversely proportional to the amount of unlabeled analyte present in the patient sample. Hormones are the most frequent analytes or antigens tested in endocrinology. However, other peptides and molecules may be measured by the same methods.

The requirements for a successful competitive binding assay are as follows:

1. *Antibody with excellent sensitivity and specificity for the analyte of interest.* Antibodies specific to the analyte of interest are traditionally raised in animal hosts. The sensitivity of the antibody must be sufficient to measure the target hormone at physiological or even subphysiological concentrations. Plasma or serum from the animal is typically used at a very large dilution (e.g., 1:250,000), so it may be used for many assays and many years. Monoclonal antibodies produced in large amounts are now commonly used for this purpose.

Laboratory techniques for recognition of endocrine disorders. In: Melmed SA, Goldfine, RJ, Koenig, AB, et al., eds. *Williams Textbook of Endocrinology.* 14th ed. Philadelphia, Elsevier; 2020:62–90.e66.)

2. *Pure hormone to use for the standard curve* (i.e., "unlabeled hormone" in Fig. 2.1; see also Fig. 2.4). In the early days of these assays, hormone for this purpose was typically purified directly from tissue (e.g., pituitary gland). With few exceptions, highly purified hormone is now produced via chemical synthesis. The hormone is diluted to concentrations encompassing the subphysiological to pathophysiological range to generate a standard (calibration) curve against which the unknown (clinical sample) is compared, and the result derived by interpolation. A "zero" concentration tube or well is typically included in the assay to assess maximum binding of the labeled hormone to the antibody in the absence of unlabeled ("competing") hormone (see left corner of the standard curve in Fig. 2.1).
3. *Labeled hormone.* The pure hormone described in #2 must be labeled in some way so it can be subsequently detected. The original RIA used radioactive isotopes to label the hormone. Although radioactive labels are still used in specific cases, many modern assays employ nonradioactive labels such as enzymes or fluorescent or luminescent compounds. Biotin-streptavidin binding is used by some methods, primarily to increase assay specificity and sensitivity.[74] One conjugated streptavidin molecule can tightly bind four biotin "signal" molecules to separate bound from free hormone, thus amplifying the final signal.
4. *Patient sample.* In early assays, the biological materials being tested had to undergo a chemical extraction and occasionally a chromatographic separation before measurement. This was particularly true if the antibody had significant cross-reactivity with similar substances, or if the matrix, or sample itself, contained compounds that could affect the kinetics of the assay. One example of such a matrix effect is plasma proteins. Many modern assays have overcome these matrix effects and now allow measurement directly in the biological material from the patient. When assaying for "total hormone" in the sample (total hormone refers to the combination of hormone bound to plasma proteins (e.g., steroids and thyroid hormone) and unbound hormone), the hormone in the biological sample must be "released" from the binding protein before testing, which can be done in several ways (e.g., addition of chemicals or heat).
5. *Incubation.* The antibody and labeled hormone are added in the same concentration and volume to each assay tube or well. Standards of known concentrations or patient samples are added in the same volume to each tube or well. This combination is mixed well and incubated at the optimal temperature and time to promote antibody–antigen binding; these parameters are determined during initial assay development.
6. *Separation.* Labeled hormone bound to the detection antibody is separated from any remaining unbound (i.e., free). There are a number of ways to do this, including adsorption to activated charcoal, use of a secondary antibody raised against (specific to) the first antibody (typically anti-IgG of the species in which the antibody was raised), or immobilization of the antibody on a solid support, such as the surface of a test tube, well, or bead.
7. *Measurement and calculation.* Once separation is complete, the amount of antibody-bound label present in the tube or well is measured. In some cases, both bound and free labeled hormone are measured from the same tube, and their ratio is used as the signal value (see y-axis of Fig. 2.1). The final step is to compare the bound labeled hormone in the standards to the amount present in the patient sample. The simplest way to conceptualize this is by looking at the dotted lines in Figure 2.1. A bound-to-free labeled hormone ratio of 0.34 interpolated to a plasma concentration of about 12 pg/mL in this case. The final plasma concentration of ACTH in this example would be 60 pg/mL, after accounting for the 1:5 plasma dilution before testing.

There are many variations on this theme, including the way the hormone is labeled and detected, how the antibody is generated, and the approach to separating labeled hormone bound to the antibody from free. However, the inverse, hyperbolic standard curve is ubiquitous. Mathematical algorithms can now fit the standard curve to an equation such that the result is automatically calculated. There is also typically a correction for nonspecific binding (tubes/wells incubated without antibody).

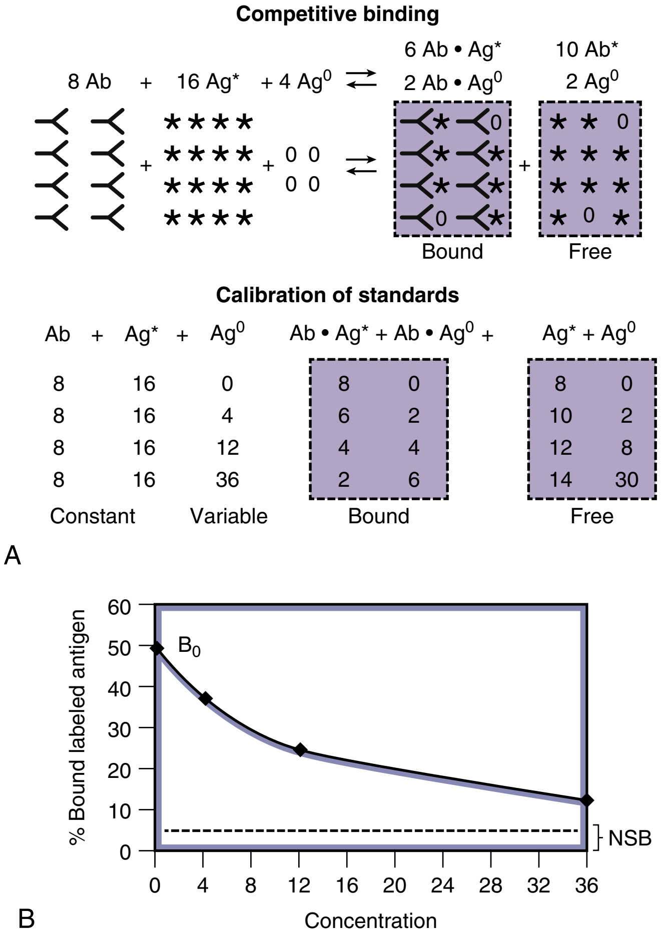

Fig. 2.4 Details about competitive binding assays. **A,** Competition of the labeled antigen (Ag*, in endocrinology, typically a hormone) and unlabeled antigen (Ag^{o}, either a calibrator or unknown sample) for a specific antibody (*Ab*) to the antigen (*Ag*) generates a dose (calibrator) response curve. **B,** B_0 represents maximum binding of Ag* in the absence of Ag^{o}. Nonspecific binding (NSB) is binding to anything except Ag. (From Sluss PM, Hayes FJ. Laboratory techniques for recognition of endocrine disorders. In: Melmed SA, Goldfine, RJ, Koenig, AB, et al., eds. *Williams Textbook of Endocrinology.* 14th ed. Philadelphia, Elsevier; 2020:62–90.e66.)

Modern Example Analytes

Many clinical assays no longer use a single antibody competitive binding approach, particularly in the case of peptides and proteins. If the hormone is large enough to have at least two epitopes against which two different antibodies can be generated, the noncompetitive immunoassay is preferable. Smaller peptide hormones, steroids, and thyroid hormones are still measured using competitive binding assays. This difference is critically important because the interpretation of the final concentrations and the interferences to which these assays are susceptible are quite different from the noncompetitive assays that will be described in the next section.

Advantages

The main advantage of the competitive binding assay is its simplicity. The basic assay design can be employed by RIA, chemiluminescent, enzyme immunoassay, and other methods. Simple, inexpensive colorimetric plate readers make the use of EIA/ELISA accessible to small laboratories. Automation on large instrument platforms provides fast and reliable results. The availability of monoclonal assays has made the development of novel competitive binding assays simple and relatively inexpensive.

Disadvantages

1. *Standard curve shape and analytic range.* Looking again at Figures 2.1 and 2.4, one can see that the dynamic range of the assay is limiting. At low unlabeled hormone concentrations, the binding of the labeled hormone can be very close to the zero calibrator. Many remember when early generations of the TSH assay could not differentiate a low-normal result and a truly low result (as in Graves disease).[75] At high concentrations, the curve becomes very flat, such that a small error in binding translates to a large error in determining the final hormone concentration. The range of 20% to 80% binding is the "sweet spot" of the curve. Low hormone concentrations may require extracting a larger volume of sample to increase assay sensitivity, whereas high concentrations may require error-prone dilutions of the sample.
2. *Cross-reactivity and interferences.* Some competitive binding assays employ the relationship between biotin and streptavidin. Biotin supplementation at supraphysiological concentrations may interfere with binding and final measurement of the analyte of interest.[76-79] Both competitive binding and noncompetitive immunoassays that use biotin-streptavidin interactions can be affected by exogenous biotin; however, they differ in the observed effects on analyte concentrations. Streptavidin is often used to bind complexes to a solid support or microparticle (Fig. 2.5). Excess biotin in the patient sample may bind the streptavidin, thereby preventing biotin-labeled antibodies from binding and creating further complexes with the analyte of interest. The detectable signal will subsequently be low. Competitive binding assays exhibit an inverse relationship between signal and analyte concentration; thus, the analyte concentration will be erroneously high. Biotin supplementation should be ruled out if laboratory results are not congruent with the clinical scenario. Note that not all assays use biotin-streptavidin interactions for analyte detection, so communication with the testing laboratory is necessary when investigating biotin interference.

The presence of cross-reacting antibodies may interfere with these types of assays. Clinical scenarios such as autoimmune disease,[80,81] alterations in protein binding concentrations,[82] and antireagent antibodies[83-86] may all contribute to assay interference. Heterophilic antibodies may also interfere with competitive immunoassays but affect noncompetitive immunoassays more frequently and are discussed later.

NONCOMPETITIVE IMMUNOASSAYS

KEY POINTS

- Two antibodies specific to different, noncompeting epitopes on the antigen (hormone) are used to label, capture, and specifically measure the analyte of interest.
- The main advantages of this approach compared to competitive immunoassays are improved specificity, sensitivity, efficiency, and availability of monoclonal antibodies.
- Its main disadvantages are interference by other factors (e.g., endogenous antibodies, biotin) and similar analytes, and a "high-hook" effect in which very high concentrations of the analyte can falsely lower the result.

Noncompetitive immunoassays, also known as immunometric assays, are primarily used to measure larger polypeptides.[3,18] The most common type of noncompetitive immunoassay is the two-site, or "sandwich," assay. These assays were originally developed as

Streptavidin-coated microparticles

Fig. 2.5 Mechanism of biotin interference with a competitive immunoassay. **A,** Sample without significant biotin contamination; signal is inversely proportional to analyte concentration. **B,** Excess biotin in the sample takes up streptavidin binding sites, thereby blocking further complex formation. Decreased signal is generated, leading to falsely increased analyte concentrations. Note that not all competitive immunoassays use biotin for signal generation. (Modified from Li J, Wagar EA, Meng QH. Comprehensive assessment of biotin interference in immunoassays. *Clin Chim Acta.* 2018;487:293–298.)

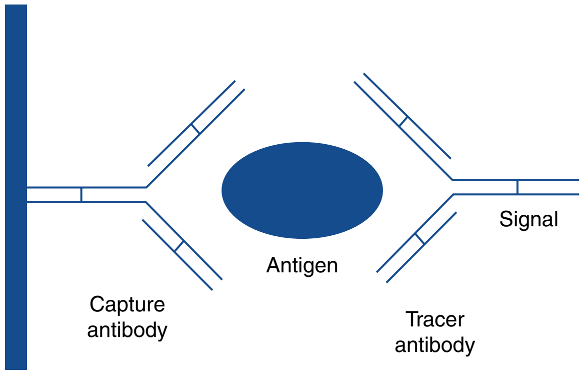

Fig. 2.6 Noncompetitive immunoassay (informally known as sandwich assays). Noncompetitive immunoassays use a capture antibody fixed to a solid phase and a tracer antibody, which has a measurable signal fixed to it, in a liquid phase. Ideally, each of these antibodies will bind a different epitope on the antigen (i.e., hormone of interest). (From Salah AK, Gharad SM, Bodiwala K, et al. You can assay that again! *Am J Med.* 2007;120:671–672.)

immunoradiometric assays, although few laboratories continue to use radioactivity as the tracer signal.[14,87]

Principle

The concept is relatively straightforward (Fig. 2.6). The analyte of interest—here called the "antigen"—is typically a polypeptide hormone or protein and must be of sufficient size (e.g., number of amino acids) to contain at least two epitopes against which two different antibodies can be generated. Antibodies may be raised against the antigen (e.g., hormone) of interest by either polyclonal/purification techniques, or, more commonly, monoclonal antibody technology (see discussion earlier in this chapter). One of the antibodies (specific for one epitope) is immobilized and is called the "capture" antibody. Mechanisms of immobilization include adsorption onto larger particles, wells, or tubes, or precipitation out of solution. The second antibody (specific for a different epitope) is in the liquid phase and is labeled so it can be detected. It is therefore called the "tracer" antibody. Frequently used labels include fluorescence, chemiluminescence, or coupled enzyme reactions. The capture and tracer antibodies are present in excess.

A standard (calibration) curve for a noncompetitive immunoassay is composed of a series of increasing concentrations of the antigen (e.g., hormone or other analyte) just as it is for competitive binding assays (Figs. 2.1 and 2.4). After incubation (for as little as 10–20 minutes!), the unbound tracer antibody is washed away, and the captured antigen is quantified via the bound tracer. The relationship between antigen and labeled antibody is directly proportional; the more hormone/analyte in the reaction, the greater the signal (Fig. 2.7). This is because the amount of "sandwich" (capture antibody–antigen–tracer antibody) formed increases in direct proportion to amount of hormone/analyte (the "meat" inside the antibody "sandwich"). Note that this is the opposite of the relationship described for competitive binding assays. Examples of endocrine analytes that may be detected by noncompetitive immunoassays are prolactin, TSH, and ACTH.

Advantages

1. *Improved specificity.* Noncompetitive immunoassays are typically more specific than competitive binding assays. This is because of the use of two antibodies in this assay design: only the full-length antigen of interest binds to both the capture and tracer antibodies. A similar antigen or antigen fragment may be bound by one (capture or tracer), but not both, and therefore would not be detected. This is particularly relevant when measuring hormones (see ACTH discussion later).
2. *Improved sensitivity.* Noncompetitive immunoassays allow for almost complete capture of antigen present, which results in superb sensitivity and analytic measurement range. Use of monoclonal antibodies in assay design also contributes to the enhanced specificity, and this combination provides better sensitivity overall.
3. *Linear standard curve.* The standard (calibration) curve (Fig. 2.7) is more linear than those of competitive binding assays (see

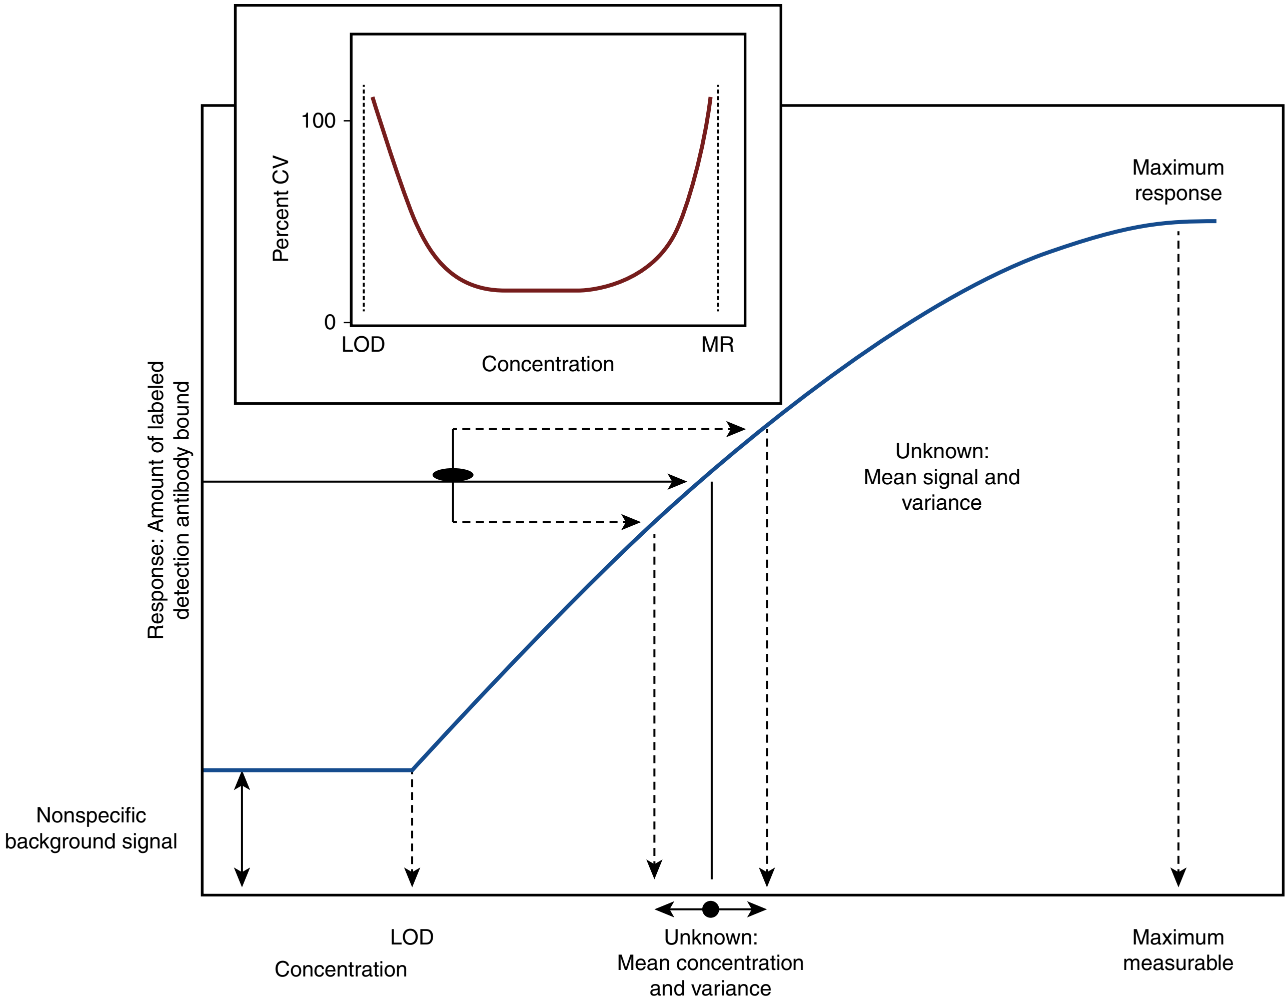

Fig. 2.7 Characteristics of the signal generated by a noncompetitive immunoassay. Signal generated by the amount of detection antibody bound to the capture–analyte complex is directly proportional to the concentration of analyte in a noncompetitive immunoassay. The concentration can be extrapolated from response (signal measured) by measuring known concentrations of "calibrators." As shown in the inset, the variance associated with measurement is heteroscedastic and increases significantly as the upper or lower limits of the assay are approached. *LOD*, Limit of detection; *CV*, coefficient of variation; *MR*, maximum response. (From Sluss PM. Methodologies for measurement of cardiac markers. *Clin Lab Med*. 2014;34:167–185, viii.)

Figs. 2.1 and 2.4), so the data reduction scheme is simpler and more reliable and has less error at the extremes of hormone concentrations. This translates into better sensitivity and analytic measurement range.

4. *Improved efficiency*. Noncompetitive immunoassays are typically fast and easily automated. These benefits can affect turnaround times and overall patient care, particularly when used for applications such as intraoperative PTH measurements during minimally invasive parathyroid adenomectomies.[88]
5. *Monoclonal antibodies are plentiful.*

Disadvantages

1. *Cross-reactivity with similar compounds*. Although noncompetitive immunoassays have improved specificity compared to competitive binding assays, immunoassays are only as specific as the antibodies they use. Cross-reactivity with similar compounds (e.g., similar hormone structure, fragment of an intact polypeptide, metabolite) can result in either positive (falsely elevated concentration) or negative (falsely low concentration) interference (Fig. 2.8). Some well-known examples include human chorionic gonadotropin assay detection of intact and/or subunits, insulin assay detection of endogenous hormone compared to exogenous analogs, and PTH

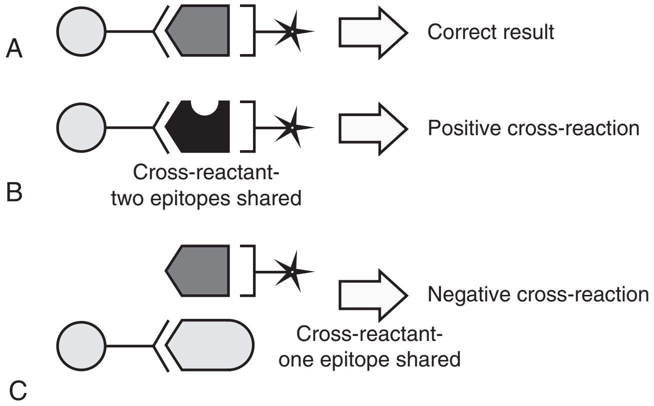

Fig. 2.8 Interfering cross-reactions in noncompetitive, two-site (sandwich) immunoassays. **A,** Correct result. **B,** Cross-reactant binds to both antibodies (shares both epitopes with antigen). **C,** Cross-reactant only binds one of the two antibodies (shares only one epitope with the antigen). (From Sturgeon CM, Viljoen A. Analytical error and interference in immunoassay: minimizing risk. *Ann Clin Biochem*. 2011;48:418–432 and From Seth J, Sturgeon CM. Pitfalls in immunoassays in endocrinology. Endocrinology and Metabolism In-Service Training and Continuing Education. 1993;11(4):89–99. with permission from the American Association for Clinical Chemistry, Inc.)

assay detection of biointact molecule or fragments. Another good example of negative assay interference by fragments is the measurement of plasma ACTH after injection of ACTH$_{1-24}$ (cosyntropin/synacthen) for ACTH stimulation testing. The high concentration of ACTH$_{1-24}$ can bind one of the assay antibodies, essentially removing it from the final "sandwich" and causing falsely low results.[65]

2. *Antibody interferences.* Patients may produce antibodies against components that are used in the immunoassays.[83-86] This interference is particularly noted for the noncompetitive, sandwich immunoassay design, but interference with competitive assays has also been documented.[89] Human antimouse antibodies in patient samples are the most frequently encountered type of human anti-animal antibody (HAAA). HAAAs may result from monoclonal antibody therapies and imaging modalities or from workplace or hobby exposure (e.g., to mice). Heterophilic antibodies, in contrast, are directed against poorly defined antigens and have weaker avidity for their target than HAAAs (Fig. 2.9).[90] Interference by either antibody type may cause *either* false positive or false negative results, depending on the specificity of the antibody. Their binding may allow for bridging across the capture and tracer antibodies (falsely elevated concentration) or may block further binding or sandwich formation (falsely low concentration). Many assays include nonimmune animal serum to "soak up" any HAAA or heterophilic antibodies that may be present in a patient sample and avoid further assay interference. However, antibody interference can still occur if they are present in large enough quantities.
3. *Biotin interference.* The ability of supraphysiological concentrations of biotin to interfere with assays that depend on biotin-streptavidin interactions for analyte detection was introduced in the competitive binding assay section. Excess biotin in a patient sample may bind to streptavidin reagent found on microparticles or solid supports (Fig. 2.10). This blocks binding of biotin-labeled antibody and further complex formation. In other words, when considering noncompetitive immunoassays, the "sandwich" cannot be

Decreased signal is generated, leading to falsely decreased analyte concentrations. Note: not all noncompetitive immunoassays utilize biotin for signal generation. (Modified from Li J, Wagar EA, Meng QH. Comprehensive assessment of biotin interference in immunoassays. *Clin Chim Acta*. 2018;487:293–298.)

formed, and the resulting signal will be low. Because of the direct relationship between signal detection and analyte concentration for noncompetitive immunoassays, the final analyte concentration will be falsely low. As with competitive binding assays, biotin supplementation should be ruled out if low laboratory results are not congruent with the clinical scenario. Note that not all assays use biotin-streptavidin interactions for analyte detection, so communication with the testing laboratory is necessary when investigating biotin interference.

4. *"High-dose hook" effect.* The assumption of the design of the noncompetitive immunoassay is that both the capture and tracer antibodies are in excess, so the more analyte in the reaction, the more "sandwich" is formed and detected. However, if the analyte concentration is dramatically increased (typically >10-fold higher than the highest standard (Fig. 2.11)), the amount of antibody can become limiting, and the assay essentially converts to a competitive binding assay. Paradoxically, this results in a (falsely) lowered result, even though very high amounts of the analyte are present in the patient specimen. This can be resolved by serially diluting the sample to lower the analyte concentration to the point where the two antibodies are now in excess (~1000 miU/mL in Fig. 2.11). Overall, this is a rare occurrence because commercial immunoassay manufacturers test for assay susceptibility to hook effect and alter their assay formulations accordingly. Although it is theoretically possible that the hook effect could lower the result into the reference interval, we have never observed this in the many assays we have performed.

Special Circumstances

Noncompetitive immunoassays are not currently amenable to the measurement of smaller molecules like steroids and thyroid hormones, because they are too small allow for generation of two antibodies to distinct parts of the molecule. As a result, immunoassays for steroids, thyroid hormones, and small peptides (e.g., oxytocin) are still measured by competitive binding assay.

The noncompetitive immunoassay design permits rapid turnaround times. The rapid PTH assay is used to intraoperatively verify parathyroid adenoma removal during minimally invasive parathyroidectomies.[88] A similar modification has been made to the noncompetitive ACTH immunoassays, allowing rapid verification of intraoperative corticotropin-secreting tumor removal.[91,92]

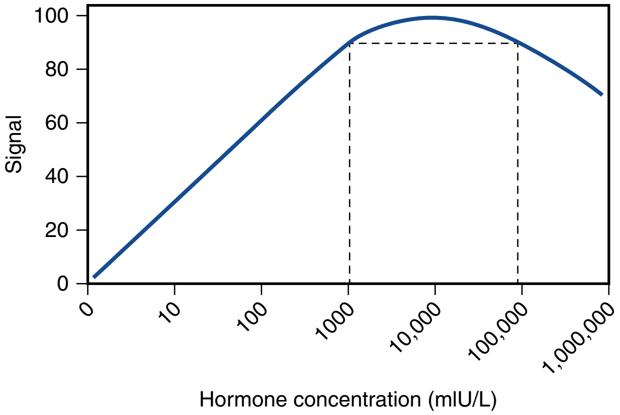

Fig. 2.11 High-dose hook effect. The response signal reaches a maximum and then decreases when the antigen concentration exceeds the limit of the noncompetitive immunoassay. (From Sluss PM, Hayes FJ. Laboratory techniques for recognition of endocrine disorders. In: Melmed SA, Goldfine, RJ, Koenig, AB, et al., eds. *Williams Textbook of Endocrinology.* 14th ed. Philadelphia, Elsevier; 2020:62–90.e66.)

Not all noncompetitive immunoassays are created equally. Each vendor may use a different set of proprietary antibodies, which can lead to discordant results between methods. For example, one noncompetitive immunoassay platform has been shown to frequently give falsely increased plasma ACTH levels, leading to unnecessary testing and even unnecessary surgery.[31-33]

A very interesting application of noncompetitive immunoassays is the use of combinations of antibodies to different epitopes on larger peptides and proteins to evaluate the presence of precursor peptides. An example is the evaluation of patients with the potential for high circulating levels of proopiomelanocortin and its posttranslational products (i.e., ACTH precursors). These typically arise from neuroendocrine tumors (e.g., small cell lung cancer) that can cause ectopic ACTH syndrome.[93] A research group has developed antibody combinations that can quantify these ACTH precursors,[87] thus enabling early detection and treatment. Unfortunately, this assay is not commercially available at this time.

FREE SERUM/PLASMA HORMONE ASSAYS

KEY POINTS

- Steroid and thyroid hormones circulate in the blood mainly bound to plasma proteins, with a small fraction in the free (biologically active) form.
- Measurement of free serum thyroid hormones and testosterone are particularly useful for clinical care.
- Methods that physically separate the free hormone from the protein bound are the gold standard.
- Calculation of the free hormone from the serum concentration of total hormone and binding protein concentration may be useful but should be used with caution.

Catecholamines and most peptides and protein hormones circulate in the plasma compartment in the dissolved (free) state. Direct measurement in serum/plasma therefore accurately reflects their biological activity. Conversely, hydrophobic thyroid and steroid hormones circulate mostly bound to proteins that have varied specificity, capacity, and affinity for the hormone (Table 2.1). The unbound (free) form binds its receptor on target cells to exert its biological effects and comprises a smaller fraction of the overall concentration. The extreme example

TABLE 2.1 Specific Plasma Binding Proteins for Steroid and Thyroid Hormones

Major Specific Binding Protein	Hormone
Corticosteroid-binding globulin (CBG)[a]	Cortisol and corticosterone
CBG and sex hormone–binding globulin (SHBG) [a,b]	Progesterone
CBG [a]	Aldosterone
SHBG[b]	Testosterone and estrogen
Vitamin D–binding protein	25OHD and 1,25(OH)$_2$D
Thyroid-binding globulin (TBG) and transthyretin	Thyroxine
TBG	Triiodothyronine

Note: All of the hormones listed bind albumin to some extent (low-affinity/high-capacity binding protein).

[a] CBG binds cortisol with higher affinity than progesterone and aldosterone.

[b] SHBG binds testosterone with higher affinity than progesterone and estrogen.

is thyroxine, which is more than 99.5% bound to plasma proteins in the circulation.[94,95] Overall, up to 90% to 95% of any given steroid hormone may actually be protein-bound. Binding proteins may be specific, high-affinity carriers (Table 2.1) or low-affinity proteins with large binding capacity (e.g., albumin, prealbumin).

Most standard assays for the measurement of steroid and thyroid hormones determine their total concentration in serum/plasma; these "total" measurements assume that the concentrations and kinetics of binding proteins are normal. There are several circumstances in which that assumption is not valid, including obesity, throughout the aging process, and during critical illness. Some additional scenarios include estrogen therapy, birth control pills containing estrogen, and pregnancy, all of which increase corticosteroid-binding globulin (CBG) concentrations and thyroxine-binding globulin (TBG) concentrations. Critical illness may decrease serum binding. Hyperthyroidism induces hepatic production of sex hormone–binding globulin (SHBG), which binds both testosterone and estrogen. These scenarios make total hormone measurements suspect and may affect reference intervals and dynamic testing cutoffs.[48,71] For example, the cutoff for a normal baseline or $ACTH_{1\text{-}24}$–stimulated serum/plasma cortisol can be significantly increased in the context of estrogen-induced increases in CBG.[96]

Serum/plasma–free hormone assays have been developed because of the issues described and because measurement of "free" hormones, at least in theory, provides the best evidence for changes in the bioactivity of the endogenous serum/plasma hormones. Some have also advocated for using salivary steroid measurements as a valid surrogate for measurement of serum free hormone concentrations.[48] Free hormone assays can be technically challenging and therefore may have limitations that must be appreciated when interpreting results in the context of the clinical scenario. Their challenging nature also dictates that free hormone tests are frequently performed in reference or specialty laboratories.

Methods for Measurement of Free Hormones

The most frequently used methods for estimating free hormone concentrations are physical separation of free from protein-bound hormone and calculations based on binding constants. Additional or historical techniques include selective precipitation, calculations including ratios, and direct antibody-based binding (immuno) assays targeted toward free hormone. Overall, these latter techniques are not recommended, and concerns regarding their use will be described later.

Free hormone is typically present in very small concentrations; thus, sensitive measurement techniques are essential. An appreciation for the complexity of measuring free steroid hormones is also critical for accurate result interpretation. Protein binding kinetics, competitive binding, and equilibrium with other binding proteins all make these measurements particularly challenging.

Physical Separation - Equilibrium Dialysis and Ultrafiltration: Physical separation of free from protein-bound fractions allows for direct measurement of the biologically active hormone. Physical separation methods such as equilibrium dialysis (ED) and ultrafiltration (UF) have long been considered the gold standard for these measurements. The analytic principle of ED is based on two solution-filled chambers separated by a semipermeable membrane; the patient specimen is located in one chamber, and an appropriate dialysis buffer is located in the other (Fig. 2.12). The membrane pores are of a sufficient diameter to allow the unbound hormone to pass through, while retaining serum-binding proteins and bound hormone. After a period of time, the free hormone from the patient sample will come into equilibrium between the two chambers. Measuring the amount of hormone that has passed from the patient sample into the dialysis buffer chamber provides the free hormone concentration. UF similarly separates free from bound hormone via a semipermeable membrane but uses centrifugation to force the molecules through. Both techniques are routinely paired with high-sensitivity MS-based methods for the final measurement of free hormone. Temperature, pH, and protein adsorption to or leakage through the membrane can all have a negative impact on the results from the ED and UF methods. Importantly, the time allowed to reach equilibrium (often 12–24 hours!) and any dilution of the sample may have a significant influence on ED measurements.

Fig. 2.12 Free hormone assay design using a dialysis membrane (often referred to as equilibrium dialysis). This allows separation of free hormone from hormone bound to plasma/serum protein. (From Sluss PM, Hayes FJ. Laboratory techniques for recognition of endocrine disorders. In: Melmed SA, Goldfine, RJ, Koenig, AB, et al., eds. *Williams Textbook of Endocrinology.* 14th ed. Philadelphia, Elsevier; 2020:62–90.e66.)

Calculation of Free Hormone Fraction: Testosterone provides the best example of estimated free (and/or weakly bound to albumin, or "bioavailable") fractions by use of calculations. Formulas for the determination of free estradiol, cortisol, and others also exist[97,98] but are not in routine use. The most frequently used formulas use measured values of (1) the hormone of interest, (2) its main binding protein (e.g., SHBG, CBG), and (3) albumin, along with their respective binding constants, to determine unbound versus bound concentrations. The accuracy of the calculated value is dependent on the accuracy of the individual measurements and the binding constants used. Automated methods exist for most of the individual components that would be included in these calculations; therefore, this approach is often more accessible for the typical hospital laboratory. Several free testosterone formulas have been published, and many studies report good correlation with ED methods.[99,100] However, differences in measurement, formulas, and constants used can lead to significant disparities among methods, and calculated values might best be considered estimates of true free hormone concentrations.[101,102] Direct (noncalculated) measurements are recommended in cases with known or suspected alternation in binding proteins.[30]

Additional Techniques

Selective precipitation of SHBG from a patient sample using ammonium sulfate has been described for the determination of free testosterone concentrations.[103] This relies on the addition of radiolabeled testosterone to the patient sample. After ammonium sulfate is added and the sample is centrifuged, the supernatant contains all non–SHBG-bound fractions (free and bioavailable). The nonbound radioactive testosterone is measured, and that percentage of the total testosterone concentration approximates the amount of bioavailable testosterone present in the sample. This method is not in routine use, largely because of the availability of ED and UF methods.

Direct (analog) immunoassay methods have been used for the measurement of free testosterone; however, these assays are unacceptable because of problems with bias, reproducibility, and hormone recovery.[29,30,99,100]

The free androgen index (FAI) is the ratio of testosterone to SHBG multiplied by 100 to obtain a percentage. Although it is a simple calculation, caution should be exercised when interpreting the FAI. Like calculations for free testosterone, accuracy of the individually measured components is central to the overall utility of the calculated value. Although there is good correlation between the FAI and physical separation techniques in females, this relationship is not ideal and not useful in males. Yet, the performance of FAI in females has been used to identify and manage patients with polycystic ovary disease.[104]

Special Circumstances

Comment on Free Vitamin D Metabolites: Like other steroid hormones described earlier, 25 hydroxyvitamin D (25OHD) circulates bound to plasma proteins. Vitamin D–binding protein (DBP) carries approximately 90% of the total plasma vitamin D.[105] Albumin carries approximately 10%, but with much lower affinity than DBP.[105] The loose binding of 25OHD to albumin renders that portion "bioavailable," which is similar to the fraction of testosterone that binds to albumin.[30] Less than 0.05% of plasma 25OHD circulates in the free form.

One may then wonder why good, direct free 25OHD or DBP assays have not been developed to allow determination of free and bioavailable serum 25OHD in a manner similar to calculated free and bioavailable testosterone.[30] This is an area of significant controversy, particularly because changes in DBP were purported to account for differences in total 25OHD observed between Black Americans and White Americans.[106] Subsequent studies questioned the validity of the DBP measurements used in this prior study[107] and, in fact, questioned the need for measuring or calculating free 25OHD in any circumstance.[108]

Comment on Salivary Hormone Measurements as a Surrogate for Free Plasma/Serum Hormones: Salivary cortisol is useful as a surrogate for free plasma/serum cortisol for the diagnosis of disorders of the hypothalamic-pituitary-adrenal axis, particularly Cushing syndrome and adrenal insufficiency.[43,109,110] Salivary cortisol may be measured by immunoassay or LC-MS/MS. For Cushing syndrome screening, immunoassay may have a higher sensitivity because of the cross-reactivity of most antibodies with salivary cortisol metabolites.[111] Immunoassay does have poorer specificity compared to LC-MS/MS, particularly in patients with mild cortisol excess owing to adrenal (ACTH-independent) Cushing syndrome.[111] The measurement of salivary cortisone by LC-MS/MS is useful for identifying contamination of the salivary sample with hydrocortisone[112] and for monitoring the adequacy of cortisol replacement therapy in patients with adrenal insufficiency.[113] Other salivary hormone analyses have been suggested, including testosterone and estrogen in the evaluation of gonadal function and 17-alpha-hydroxyprogesterone in the early evaluation of congenital adrenal hyperplasia because of 21-hydroxylase deficiency.[114-117] Furthermore, a new, completely noninvasive nasal ACTH stimulation test using salivary cortisol as an outcome has been proposed.[50] This could make the evaluation of adrenal insufficiency simpler and available to primary care physicians in any clinical setting.

PLASMA RENIN ASSAYS

KEY POINTS

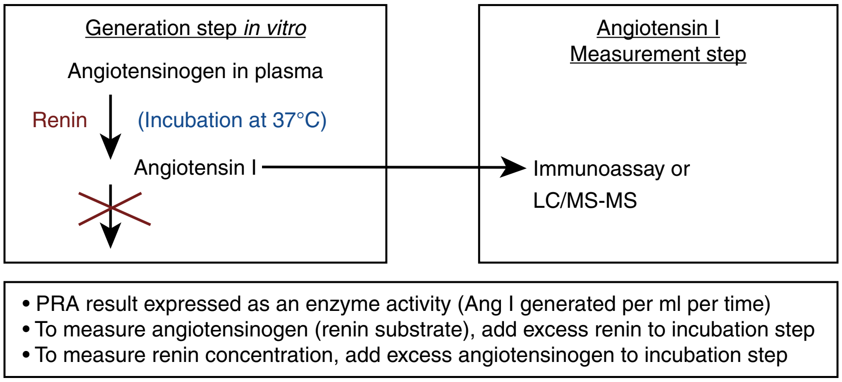
- Plasma renin can be measured as plasma renin activity (PRA; measurement of angiotensin I generation *in vitro*) or direct renin concentration (DRC) by noncompetitive immunoassay.
- The main advantage of PRA is that it assesses the actual endogenous biological activity of renin.
- The main advantages of DRC are that it is simple and high-throughput, and is not influenced by changes in plasma angiotensinogen concentrations.

Renin is not a hormone in the classic sense: it is an enzyme that catalyzes the cleavage of angiotensin I (a small peptide) from angiotensinogen ("renin substrate"). There is considerable confusion about how plasma renin is measured.

Endocrinologists should take the lead in teaching the medical community the proper pronunciation of the word "*renin*" (i.e., REE-nin; as in "REE-nal" artery). The mispronunciation of the word renin as "WREN-in" is incorrect and imprecise, and it is up to us to correct this common (annoying) error.

Plasma Renin Activity Assay and its Modifications

Plasma renin *activity* (PRA) is measured by a hybrid assay that is part bioassay (generation of angiotensin I *in vitro*) and typically part immunoassay (the measurement of angiotensin I generated *in vitro*) (Fig. 2.13).[118] The first step is the *in vitro* 37° C generation of angiotensin I from the plasma renin and angiotensinogen contained in the patient's sample. Reagents are added that prevent the breakdown of angiotensin



Generation step in vitro

Immunoassay or LC/MS-MS
• PRA result expressed as an enzyme activity (Ang I generated per ml per time)
• To measure angiotensinogen (renin substrate), add excess renin to incubation step
• To measure renin concentration, add excess angiotensinogen to incubation step

Fig. 2.13 Simplified version of the plasma renin activity assay. The first step generates angiotensin I from endogenous (patient) angiotensinogen and renin. The X represents inhibitors that are added to prevent degradation of angiotensin I during the generation step. The second step is the measurement of angiotensin I concentration. *LC-MS/MS*, liquid chromatography tandem—mass spectroscopy; *Ang I*, angiotensin 1; *PRA*, plasma renin activity.

I *in vitro*. A parallel sample incubation on ice (4° C) is commonly done to correct for the endogenous angiotensin I in the plasma sample. Once the angiotensin I generation step is complete and the reaction is stopped, the next step involves angiotensin I concentration measurement by immunoassay or LC-MS/MS.[119,120] The result is expressed as a biological activity (e.g., pmol of angiotensin I generated per minutes of incubation per liter of plasma). Because angiotensinogen concentration is in excess in the typical patient sample, the angiotensin I generated (renin activity) is dependent only on the concentration of renin in the sample. The PRA assay can be modified to measure plasma angiotensinogen "concentration" (Fig. 2.13). This is accomplished by adding renin in excess in the incubation step.[119] Plasma renin concentration can be measured by adding excess angiotensinogen in the incubation step.[119] In both cases, the measurement of angiotensin I concentration generated is the final step.

Advantages

The main advantages of the PRA assay are (1) the decades of experience with the interpretation of the results and (2) assessment of the actual bioactivity of renin within the sample.

Disadvantages

The PRA assay is tedious and time-consuming. If there is an alteration in angiotensinogen concentration, it can become rate-limiting in the generation step. This can also be considered an advantage because if angiotensinogen is rate-limiting *in vitro*, it is likely to be rate limiting *in vivo*.

Direct Renin Concentration

With the development of the two-site immunometric (noncompetitive) assay, it is now possible to directly measure plasma renin concentration.[121] This method is fast and inexpensive and correlates well with PRA.[122-124] Many reference laboratories offer both PRA and direct renin concentration because many clinicians are used to PRA in the assessment of primary aldosteronism using the plasma aldosterone to renin ratio.[124,125] The main disadvantage of the method for measuring direct renin concentration is that is it not a bioassay and is unaffected by potentially rate-limiting low concentrations of angiotensinogen in the patient's circulation.

STRUCTURAL ASSAYS—MASS SPECTROMETRY

KEY POINTS

- After an initial physical separation of the compound of interest (typically by liquid chromatography), mass spectrometry is used for detection.
- Mass spectrometry uses transformation of the compound into charged molecular ions, and then separation, fragmentation, and measurement of the ions according to their mass-to-charge ratio.
- Advantages include the ability to measure only the compound of interest (high specificity) and the ability to detect low concentrations (sensitivity).
- Disadvantages include instrument and maintenance costs and the technical expertise required.

Mass spectrometry instruments used in clinical laboratories include two main types: gas chromatography-mass spectrometry (GC-MS) and LC-MS/MS. Both techniques rely on the physical separation of compounds on chromatography columns, the transformation of these compounds into charged molecular ions, and then separation, fragmentation, and measurement of these in the mass spectrometer.[19-23] Ions are separated according to their mass-to-charge ratio (m/z), which is a dimensionless quantity calculated by dividing the mass number of an ion by its charge state.

Gas Chromatography—Mass Spectrometry

GC-MS has been widely used in steroid chemistry and is still the main technique used for the identification and characterization of inborn errors of steroid metabolism.[126] Steroid profiling developed over 40 years ago, opening up the field of urinary steroid profiling, which is now sometimes referred to as urinary steroid metabolomics.[127] GC-MS owes its success to the efficient separating capability of very long fused silica capillary columns coupled with the specificity of a mass detector. With this combination, the identification of structurally-related steroids can be achieved. Chromatographic separation of steroids is crucial, because there are many steroids with similar m/z values that will appear identical to the mass spectrometer. Good examples of this include 11-deoxycortisol, corticosterone, and 21-deoxycortisol, which share a parent ion m/z of 347 and also fragment to give the same daughter ions.[128]

The main problem with GC-MS is the need to chemically derivatize steroids before analysis, because only highly volatile molecular ions will travel through the instrument. To achieve this, derivatized steroids are vaporized and are carried by inert gas through a heated silica column and interact with the chemically bonded stationary phase attached to the walls of the column. Gaseous to stationary phase interactions based on the differences in hydrophobicity of the individual steroids cause differences in retention of steroids on the column, so they arrive at the detector at different times. Derivatization also improves steroid stability and allows optimal sensitivity and chromatographic separation.[129] GC-MS has an advantage over other techniques in that it is able to measure a wide variety of steroids and their metabolites simultaneously within the same analytical run. Run times are typically 30 minutes or longer, and the sample preparation steps are long and tedious, but the data that are eventually generated are unmatched by any other technique, because novel and unknown compounds can be identified.[126] It is the ability to search for previously unidentified steroids and generate metabolic fingerprints from the interrelationship of steroids that make this technique so powerful for the investigation of steroid disturbances.

The main weakness of GC-MS is the inherent complexity of sample preparation, which makes it a difficult technique to use. The introduction of electrospray ionization and improvements in liquid chromatography have propelled LC-MS/MS to the forefront of separation techniques. Indeed, it has largely superseded GC-MS in both routine and research laboratories. Differences between the two techniques are marked, and each have specific advantages. GC-MS confers the ability to screen for all compounds in a sample, whereas LC-MS/MS relies on targeted analysis of known compounds, so in the case of LC-MS/MS, the analyst will only detect what they expect. This is an important consideration because although LC-MS/MS is unmatched for quantitation of targeted steroids, so far it cannot replace GC-MS for discovery research.[26] This is a situation that may change with improvements in LC-MS/MS technology, including supercritical fluid chromatography[26] and the use of accurate mass instruments.[130] However, LC-MS/MS generally does not need derivatization, so sample preparation is simpler, and the run times are much shorter, allowing for faster throughput.

Some sample preparation is still required, because neat serum, urine, or saliva samples cannot be injected directly into the LC-MS/MS system. The main ways of preparing samples to remove proteins and other interfering substances include simple protein precipitation and liquid or solid phase extraction.[131] The latter two techniques are more suitable for high-sensitivity work, where significant sample clean-up, matrix removal, and possibly analyte concentration are needed.[128] The workflow is therefore much simpler than the GC-MS workflow, and this makes LC-MS/MS much more amenable for use in a routine clinical laboratory. However, the high cost of instrumentation and greater technical complexity, requiring highly skilled technical staff, has impeded the wider adoption of LC-MS/MS. As a consequence, some laboratories tend not to use LC-MS/MS and still depend on manual or fully automated immunoassays for many analytes.

Liquid Chromatography—Tandem Mass Spectrometry

LC-MS/MS uses a liquid mobile phase to achieve chromatographic separation on a short packed column. The mobile phase may contain salts or weak acids to enhance ionization in the source, and the column packing material is chemically bonded with a variety of ligands to make it hydrophobic in nature. Separation occurs by hydrophobic interactions between the analyte, the column packing material, and the mobile phase. Samples are injected as a liquid onto the column, and different analytes are separated according to their relative retention on the column and consequently reach the detector at different times. Chromatographic separation is still important to discriminate between compounds with identical mass.[131] Electrospray ionization was a breakthrough, because it converts the column effluent from a liquid containing molecules into gaseous ions, thus enabling their passage through the mass spectrometer. The free ions generated are drawn into the mass spectrometer and separated according to their m/z using quadrupoles, fragmented in a collision cell, and then detected.[132]

Analytical specificity in GC-MS is determined by chromatographic separation on a very long column and measurement of molecular ions, whereas for LC-MS/MS specificity is achieved in a three-stage process. First, some crucial separation is achieved on the much shorter analytical column sufficient to separate compounds with the same m/z. Second, specificity is augmented by selecting the molecular ion formed in the ionization source from other potentially interfering ions using a quadrupole mass analyzer. Third, the molecular ion is selectively fragmented in the collision cell, after which molecular ion fragments are selected using the second quadrupole mass analyzer and then measured in the detector. The capacity to select a parent and a daughter ion after a chromatographic separation makes LC-MS/MS both highly sensitive and specific.

The molecular ion is often capable of forming several abundant fragment ions, and additional quality checks are now commonly incorporated by monitoring a second qualifier fragment ion to assess interference in the method. It is the fragment ions that are measured in the detector, having been produced by selectively fragmenting a molecular ion that has undergone prior separation on a chromatography column. (Fig. 2.14). This may seem complicated, but the instrument is under full software control, and each step is fully automated and highly reproducible. Once set up, the instrument can be left unattended for

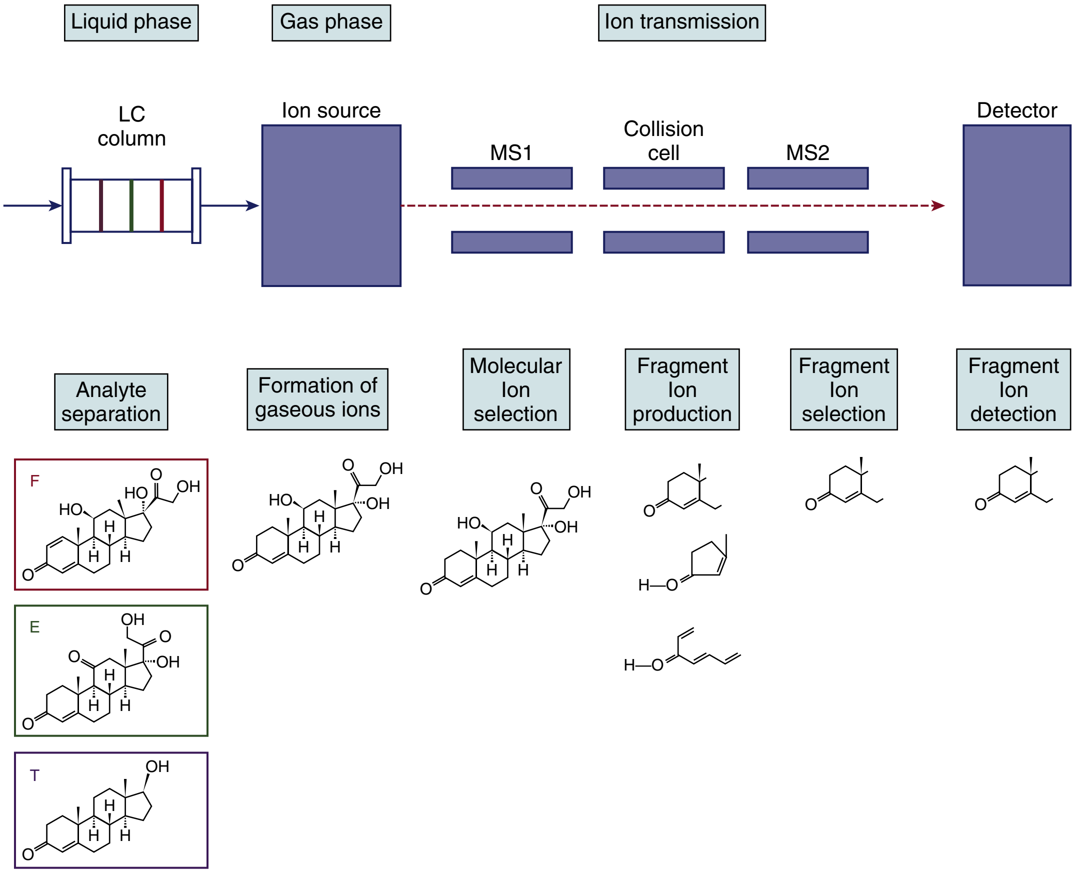

Fig. 2.14 Diagram showing the measurement of cortisol using liquid chromatography tandem-mass spectroscopy. Cortisol (F), estradiol (E), and testosterone (T) are first separated using liquid chromatography. Cortisol elutes first from the column, it is ionized in the mass spectrometer source, and the cortisol ions are selectively transferred through the first quadrupole to a collision cell. Cortisol is fragmented in the collision cell, and an abundant fragment ion is selectively transferred through the second quadrupole for measurement in the detector. *LC*, liquid chromatographer; *MS*, mass spectrometer.

long periods of time, including overnight and weekends, and the results downloaded to the laboratory information system for reporting. Both MS techniques are superior to immunoassay methods in terms of specificity and also because of the sample clean-up steps.

Between-assay variability: LC-MS/MS is well placed for the development of niche assays that are performed less frequently, are unavailable, or perform poorly on immunoassay platforms. Some of these niche assays include the less commonly measured steroids such as 11-deoxycorticosterone (11-DOC), aldosterone, 17-hydroxyprogesterone (17-OHP), dehydroepiandrosterone, and dihydrotestosterone. There is the possibility of an immunoassay being withdrawn abruptly from the market because of quality or regulatory issues. Another important consideration is the reproducibility of immunoassays over time because of calibration or reagent changes, which can cause problems with diagnostic cutoffs in routine laboratory procedures and in longitudinal research studies.[133] However, just as there are poorly performing immunoassays, there are also poorly performing LC-MS/MS methods, and this has been shown in interlaboratory surveys for a number of steroids.[134] The main problems are related to the choices of sample preparation technique, chromatography columns, and internal standards, all of which can hinder minimizing sample matrix effects. Interlaboratory variability can often be improved by standardizing sample clean-up and chromatography conditions, because it is typically not the MS measurement technique that is at fault. Improvements in interlaboratory performance have also been achieved by the availability of commercially available calibration material.[135] The steroids that are infrequently measured, such as 17-OHP, tend to have the worst comparative performance between laboratories.[136] Improvements in interlaboratory variability have been achieved with accuracy-based initiatives such as the Centers for Disease Control and Prevention (CDC) hormone standardization program and vitamin D standardization certification program.[137,138] Central to this strategy is the use of LC-MS/MS to assign target values to single-donor patient serum or plasma samples that can then be distributed to laboratories for analysis. Having a true assigned target concentration allows assessment of bias from the true result in a clinical sample. LC-MS/MS assigned target values have since been adopted by many national external quality assessment schemes, but, as in the CDC program, only for a limited number of steroids.

Liquid Chromatography—Tandem Mass Spectrometry Applications

Cortisol: In most laboratories, cortisol is measured by immunoassay, but LC-MS/MS is a useful alternative technology, as it is not affected by cross-reactivity of synthetic exogenous glucocorticoids such as prednisolone/prednisone, methylprednisolone, and cortisol precursors and metabolites such as 11-DOC. Some cortisol immunoassays are also less effective at freeing cortisol from CBG, as demonstrated by recovery in women taking the oral contraceptive pill.[139] Variability between assays will affect how the cortisol result is interpreted against existing reference intervals, so the clinician should be aware of the assay characteristics of their local laboratory. From a practical standpoint, rapid LC-MS/MS assays for the routine measurement of serum cortisol are now available, with the added benefit of identifying samples that show evidence of exogenous steroid use.[140] LC-MS/MS can also provide the added value of simultaneously measuring dexamethasone with cortisol to determine if a patient has absorbed the drug or metabolized it quickly, when interpreting dexamethasone suppression tests.[141]

Estradiol: Many estradiol (E2) immunoassays perform poorly for the measurement of samples from men, children, and postmenopausal women,[142] because of a lack of sensitivity and the cross-reactivity with some drugs, particularly the estrogen receptor antagonist fulvestrant.[143] Achieving the necessary sensitivity to measure E2 using LC-MS/MS has been challenging, but improvements in instrumentation have enabled the development of assays capable of measuring concentrations as low as 0.6 pmol/L,[144] which meets the required sensitivity of 1 pg/mL (3.7 pmol/L) advocated by the Endocrine Society.[97] It is also important to measure E2 in postmenopausal women taking aromatase inhibitors, because treatment can reduce serum E2 by 85%; such depletion may be an efficacy or safety biomarker of adjuvant aromatase inhibitor treatment.[145]

Vitamin D: Automated immunoassays have proved unreliable in a number of patient groups, including pregnant women, intensive care patients, patients with liver failure, hemodialysis patients, and osteoporotic patients.[146] LC-MS/MS is the recommended method in these patients because of its superior specificity. In addition, immunoassays do not distinguish between 25(OH)D_2 and 25(OH)D_3 and suffer from cross-reactivity with other vitamin D metabolites recognized by the antibody, such as 24,25$(OH)_2$D.[146] Many of the earlier LC-MS/MS methods for vitamin D were developed for speed and sample throughput, and also suffered from some interference. Separation of 25(OH)D_3 from the C3 epimer of 25(OH)D_3 could not be achieved. This may be a problem in neonates, where concentrations can be high but typically return to adult levels of less than 10% of total vitamin D by 3 months of age.[147]

Peptides: Smaller peptides such as angiotensin 1 (Ang 1) are easily measured using LC-MS/MS and can be used in a routine hospital laboratory setting. Larger peptides such as insulin-like growth factor 1 and thyroglobulin offer a greater analytical challenge, because they invariably need to be digested with proteolytic enzymes to produce manageable fragments for the mass spectrometer to measure.[148] Thyroglobulin measurement by LC-MS/MS after protein digestion is the method of choice for many large contract laboratories because it is free from thyroid antibody interference.[149]

As mentioned previously, PRA is typically measured by immunoassay of Ang I generation but may also be measured, following a suitable incubation step, by LC-MS/MS.[120] LC-MS/MS methods provide sensitive interference-free measurement of Ang I and offer a good alternative to immunoassay-based methods.[150]

Multiplexed Liquid Chromatography—Tandem Mass Spectrometry

Another advantage of LC-MS/MS is the capability to simultaneously measure several different analytes to produce multiplexed test panels. Performing multiplexed analysis is often a minimal extra expense, because the sample preparation and LC-MS/MS conditions are the same. Selective testing panels have been developed to investigate different clinical conditions, such as second-tier testing for congenital adrenal hyperplasia (CAH)[151] to supplement newborn screening programs and for the investigation of adrenal insufficiency.[152] Commercially available kits have been developed for the measurement of steroid panels (www.Chromsystems.com), and the introduction of easy-to-use kits has already simplified the introduction and service delivery of LC-MS/MS in routine laboratory procedures.

Multiplexed LC-MS/MS panels have recently allowed a more thorough investigation of conditions such as polycystic ovary syndrome (PCOS)[153] and CAH.[154] There is increasing interest in the measurement of not only testosterone, but other androgens such as androstenedione and the 11-oxygenated steroids such as 11 ketotestosterone (11KT).[155] The evidence for the use of other androgens in screening for CAH is also compelling, and 11KT may prove to be an effective androgenic marker in this condition.[156]

Some have also advocated the measurement of 21-deoxycortisol as a discriminator between 21-hydroxylase deficiency and PCOS in women with hyperandrogenism.[157] Diagnostic uncertainty often arises in these cases, because the clinical presentations of nonclassical CAH and PCOS are similar, and 17-OHP (the traditional marker for CAH) may also be elevated in PCOS.

Multiplexing tests in a single assay may confer benefits, but it can also generate large amounts of complicated data that need to be carefully interpreted. The development of urine steroid metabolomics for discriminating benign from malignant adrenal tumors has shown that this problem can be solved with the use of artificial intelligence.[127,158] Urine steroid profiling, first developed using GC-MS, has been shown to predict adrenocortical carcinoma with 95% sensitivity and specificity and can achieve an early diagnosis. The analysis has since been transferred from GC-MS to LC-MS/MS using fewer steroids in the panel with an increase in sample throughput but, crucially, with no detriment to the test performance. Other diagnostic areas likely to benefit from this approach include the differentiation of adrenal from pituitary Cushing syndrome, and the diagnosis of CAH.[130] There is also some promising work on the use of multiplexed LC-MS/MS assays coupled with machine learning in the investigation of Cushing syndrome[159] and pheochromcytoma.[160] Machine learning represents a great advance that reduces the need for expert highly subjective interpretative skills.

Special Circumstances

Urine used to be the sample of choice for measuring steroids and biogenic amines, because the larger concentrations found in urine were necessary to overcome sensitivity problems in older assays. However, 24-hour urine samples can be challenging for the patient to collect correctly and for the laboratory to process, so some urine tests are gradually being replaced by serum tests (e.g., for metanephrines[161] and 5-hydroxyindoleacetic acid[162]). Indeed, plasma metanephrines are now the method of choice for the investigation of paraganglioma,[163] because metanephrines are continuously secreted by the tumor and are readily measured using LC-MS/MS.

Saliva offers benefits because it is easy to collect, it can be collected by the patient at any time of day and can be collected frequently. However, saliva collection is not without contamination problems, arising mainly from topical steroid use.[112] Metabolism of steroids occurs in the salivary glands, allowing the use of salivary cortisone as a surrogate marker for serum free cortisol.[113] Salivary cortisone is technically easier to measure than cortisol by LC-MS/MS, because it is present in greater than 4-fold concentrations, closely reflects free serum cortisol after adrenal stimulation, and is unaffected by CBG changes. LC-MS/MS analysis of late-night salivary cortisol or cortisone does not improve the already excellent sensitivity of late-night cortisol by immunoassay, but does improve specificity of the test.[111] Post dexamethasone salivary cortisone may be a better discriminatory marker between healthy subjects and patients with Cushing syndrome or with autonomous cortisol secretion than salivary cortisol.[141] In addition, salivary cortisone is an excellent marker for contamination of the saliva sample by topical hydrocortisone (cortisol).[112] Although technically inferior to LC-MS/MS, cross reactivity with other corticosteroids may actually improve the diagnostic performance of immunoassays.[164] Metabolomics programs are beginning to generate new candidate diagnostic markers based on multiplexed LC-MS/MS methods.[165]

Fully automated clinical mass spectrometry analyzers are finally beginning to appear on the market, but currently have a limited test repertoire and are relatively expensive, a position analogous to the introduction of laboratory automation for immunoassay 30 years ago. These instruments are less technically demanding, will bring LC-MS/MS to a wider range of laboratories, and should eventually improve the availability of high-quality tests to the clinician.

SUMMARY AND FUTURE DIRECTIONS

Clinicians depend on accurate and reproducible hormone measurements for the diagnosis, treatment, and management of patients with endocrine diseases. Since the development of the RIA, many improvements have been made that increase throughput and reduce errors. However, it is incumbent on clinicians to be aware of the potential for preanalytic and analytic errors in all measurements obtained. Clinicians should be attuned to the reference intervals for the result obtained, as they can vary significantly between laboratories and methods. When a result is obtained that does not fit with the clinical scenario, clinicians should repeat the measurement and, if needed, work with their clinical laboratory partners to resolve the issue. When possible, referring a sample to another laboratory for analysis by an alternate method may be useful. All assays have strengths and weaknesses, including susceptibility to interferences such as similar hormones and metabolites and other factors such as biotin and heterophile antibodies.

LC-MS/MS is emerging as the method of choice for small molecules—particularly steroids—although this approach is very labor-intensive, requires sophisticated instrumentation and technical expertise, and also has analytic strengths and weaknesses. The development of methods to measure multiple steroid metabolites in a single sample by multiplexed LC-MS/MS has promise to evaluate diseases that are difficult to diagnose and manage, such as adrenocortical cancer and PCOS. The development of accuracy-based quality control schemes for more analytes will clearly improve agreement between laboratories and between different methods. Finally, education of clinicians as to the strengths and weaknesses of the methods for measuring hormones is a mission that will continue to improve clinical care.

INTRODUCTION

In 2017, the Nobel Prize in Physiology or Medicine was jointly awarded for the discovery of the molecular mechanisms that control the circadian clock. In announcing the prize the Nobel Committee described how the work of Jeffrey C. Hall, Michael Rosbash, and Michael W. Young explains "how plants, animals and humans adapt their biological rhythm so that it is synchronized with the Earth's revolutions."[1] Adaptation of life to the length of each day had proven to be literally "in our genes."

What Are Biological Rhythms?

Biological rhythms are natural oscillations that occur in physiology and behavior that respond to periodic changes in the environment. They can be described by their length and by the circumstances in which they occur. Humans and many other animals have a *diurnal* behavior rhythm reflecting more activity during daylight hours, and rest or sleep at night. By contrast, *nocturnal* species such as rodents are active at night and rest during the day. Rhythms with longer periods such as annual migration or the human menstrual cycle are *infradian,* whereas rhythms that occur within a period of minutes to hours are *ultradian.*

Rhythms that are endogenous, self-sustained, and approximate a 24-hour day, are termed *circadian*. In mammals this includes secretion of many hormones, most notably cortisol and melatonin. Circadian rhythms are entrained or synchronized to external cues (*Zeitgebers*, from the German "time giver"), and in humans and other mammals the most potent of these are light and timing of food.[2] The most important point is that circadian rhythms are *intrinsic*—they continue to oscillate even in the absence of a *zeitgeber* or synchronizing input.

KEY POINTS

- Measurement of melatonin in dim light conditions is considered the gold standard measure of circadian phase. Melatonin secretion is extremely sensitive to light, which may alter the phase of the rhythm or temporarily suppress secretion.

The Sleep-Wake Cycle as a Rhythm

The sleep-wake cycle is perhaps the most obvious and visible behavioral manifestation of a circadian rhythm in humans, having evolved as a consequence of the earth's 24-hour rotation. Characterized by a temporary suspension of consciousness, sleep is nevertheless associated with a multitude important and dynamic processes.[3] Bordered at the onset by the rise of the "sleep hormone" melatonin and at the offset by an anticipatory rise in the hormone cortisol (Fig. 3.1), sleep occurs as a series of *ultradian* stages, with each cycle lasting approximately 90 to 120 minutes.[3] Accompanying these cycles is a complex array of physiological events, including changes in sympathetic output, fluctuations in body temperature and muscle tone, and the secretion of hormones like growth hormone and aldosterone.[4,5] Disturbance of the sleep rhythm, either in time or structure, results in adverse health outcomes for the individual.[6]

Clocks in the Brain and the Periphery

We have already noted that circadian rhythms are *intrinsic,* and therefore their period persists in the absence of external cues. The mechanisms by which internal time is maintained depend on a network of intracellular clocks, coordinated by a central pacemaker in the suprachiasmatic nucleus of the hypothalamus (SCN). The SCN consists of tiny bilateral nuclei of a few thousand cells each—the cells are tightly

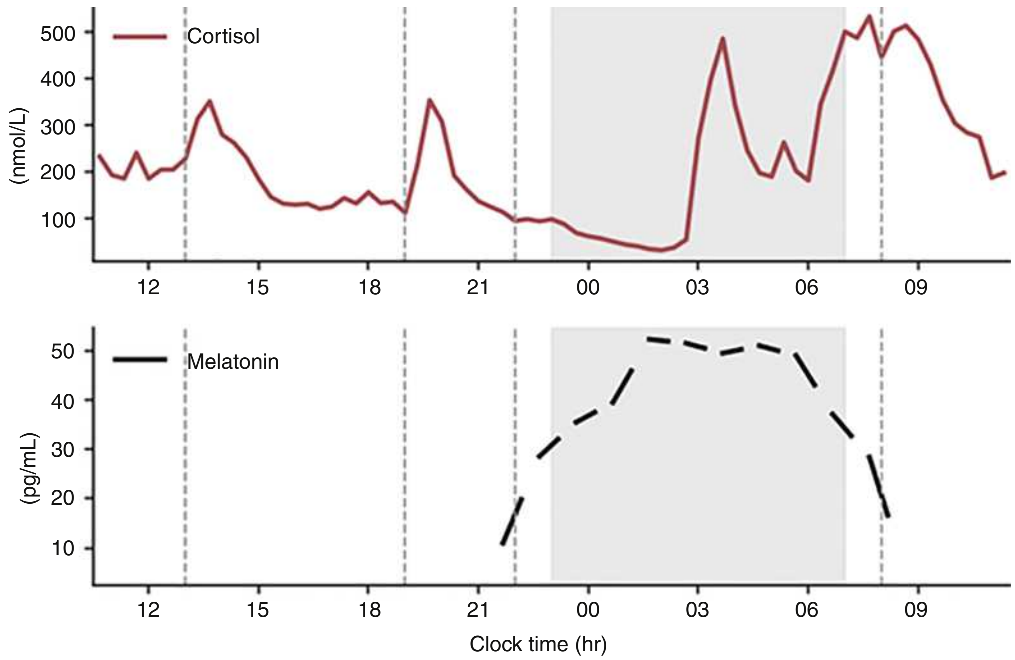

Fig. 3.1 Illustrative example of the daily rhythms of two circadian hormones—cortisol and melatonin. In this experiment, a healthy male volunteer was admitted to the research facility, and plasma samples were taken every 20 minutes during a 25-hour routine in which ambient light, meals *(vertical dashed lines)*, and sleep times *(shaded areas)* were controlled. Both the diurnal and ultradian rhythms of cortisol *(top panel, red)* can be observed. Following the nadir, pulsatile secretion begins around 3:00 AM, with peak levels just after waking. In dim light conditions (<10 lux ambient light) melatonin *(bottom panel, dashed lines)* begins to rise in the evening, peaks during sleep, and falls to undetectable levels soon after waking. (Source: Author's own data [unpublished].)

coupled, and output oscillates with a free-running period of close to 24 hours. Light information conveying time of day reaches the SCN via the direct synaptic connections from projections of specialized photosensitive retinal ganglion cells along the retinohypothalamic tract. The traditional view of the circadian timing system in mammals was to assume that the SCN was the only tissue capable of generating self-sustaining oscillations. In this model, the vast majority of peripheral tissues acted as subservient "slaves" to the master clock.[7] It has only been in the very recent past that scientists have discovered that, in fact, molecular clocks are present in almost all cells and tissues of the body, and that the SCN functions to coordinate and synchronize these rhythms.[8]

ENDOCRINE RHYTHMS

An endocrinologist's job is to concern themselves with the diagnosis and management of conditions affecting endocrine glands and hormones. Even though almost all hormones show rhythmic time of day variation, even in disease states, clinicians are typically required to interpret and extrapolate information about disorders based on single or limited time series samples. These timepoints for sampling almost always converge in the morning, which is generally the most convenient for clinicians and laboratory staff, but do not necessarily correspond with the best time for diagnostic value—the peaks and troughs in the hormone or hormones being considered. Interindividual variation in circadian and behavioral timing results in very broad "normal" ranges that can be very difficult to interpret.

Examples of Endocrine Rhythms in Humans

The examples of human endocrine rhythms are numerous. In this review we will focus on the oscillations of glucocorticoids that have both *circadian* and *ultradian* rhythmicity, but it is worth mentioning a few others by way of example. Melatonin is a *circadian* hormone, secreted by the pineal gland and in humans heralds the onset of sleep. Secretion begins in the evening, peaks during sleep, and falls to low or undetectable levels during daylight waking hours. Measurement of melatonin, when the onset is measured under dim light conditions,[9] is considered the benchmark method of circadian phase determination in humans. Melatonin has effects that go substantially beyond conveying timing information to body tissues. There is an increasing evidence to suggest that melatonin plays an important role in the modulation of key metabolic processes, including glucose regulation and energy balance.[10,11] Glucose and insulin themselves have *diurnal* and *ultradian* periods, and evidence from studies in humans and rodents suggests that "eating against the clock"—that is, at metabolically unfavorable clock times—contributes to the onset of metabolic dysfunction and diabetes.[12]

Ultradian rhythms are very frequently superimposed upon rhythms of longer periods. In endocrinology, pulsatile ultradian secretion is a characteristic feature of most hormones, including growth hormone,[13] insulin,[14] and the reproductive axis,[15,16] as well as the pulsatile secretion of glucocorticoids.[17–20]

The Hypothalamo-Pituitary-Adrenal Axis as a Model Endocrine Rhythm

The synthesis and secretion of glucocorticoid hormones occurs under the control of positive and negative feedback loops that exist between the hypothalamus, pituitary, and adrenal glands—the so-called hypothalamo-pituitary-adrenal (HPA) axis. Stimulated by the release of adrenocorticotropic hormone (ACTH), glucocorticoids exert multiple effects, including regulation of growth, metabolism, and the

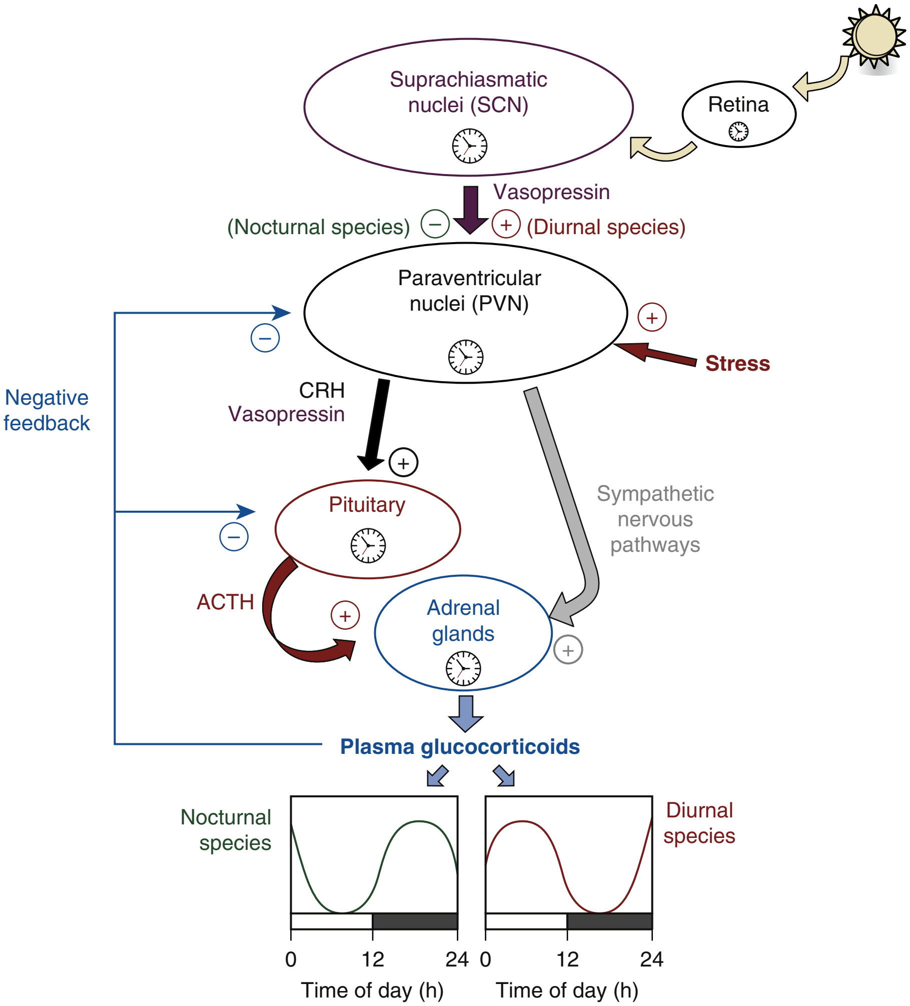

Fig. 3.2 Representation of the control of circadian glucocorticoid release in mammals. The circadian secretion of glucocorticoids is dependent on the rhythmic release of adrenocorticotropic hormone (*ACTH*) and a gating process by the adrenal clock. Clock symbols represent self-sustained oscillators. Rhythmic activity of the hypothalamo-pituitary-adrenal axis regulated by the central clock in the suprachiasmatic nuclei (*SCN*), which is entrained by ambient light that is received via the retina. *PVN,* Paraventricular nuclei; *CRH,* corticotrophin-releasing hormone. (Modified from Oster H, Challet E, Ott V, et al. The functional and clinical significance of the 24-hour rhythm of circulating glucocorticoids. *Endocr Rev*. 2016;38:3–45.)

stress response—their action is mediated through the near-ubiquitous presence of glucocorticoid[21] and less widely distributed mineralocorticoid[22] receptors in central and peripheral tissues. In humans, the circadian rhythm of cortisol peaks just before waking, anticipating the start of the new day.[23]

KEY POINTS

- The synthesis and secretion of glucocorticoid hormones is under the control of the hypothalamo-pituitary-adrenal axis, which exhibits both a diurnal circadian and an ultradian rhythm. The expression of genes and gene transcripts is influenced by the pattern of glucocorticoid exposure, and several human diseases are associated with abnormal glucocorticoid pulsatility.
- Sleep is characterized by cycles of rapid eye movement and nonrapid eye movement stages, whose gold standard measurement is polysomnography. Sleep is regulated both by a homeostatic process, driven by sleep debt, and a circadian process, regulated by the central pacemaker in the suprachiasmatic nuclei.

The ACTH secretory rhythm is coordinated by inputs from the SCN, which project to the paraventricular nucleus of the hypothalamus (PVN). The SCN is thus able to regulate corticotrophin-releasing hormone (CRH) from neurons in the PVN, and therefore release of ACTH from the anterior pituitary.[24] Further, in the presence of metyrapone, which temporarily suppresses endogenous cortisol production, and under conditions of constant CRH infusion, there is still a circadian rhythm of ACTH secretion, suggesting a role for other hypothalamic mediators such as vasopressin.[25]

The responsiveness of the adrenal gland to ACTH stimulation depends on the phase of the circadian cycle,[26] and, in addition, peripheral "clocks" located in the adrenal cortex can be entrained by light, likely via neuronal connections of the autonomic nervous system.[26,27] Thus, the circadian rhythm of glucocorticoids, entrained by the SCN, is modulated at the level of the adrenal both through inputs from the sympathetic nervous system, and by intrinsic adrenal mechanisms that "gate" sensitivity to ACTH stimulus depending on the time of day (Fig. 3.2).

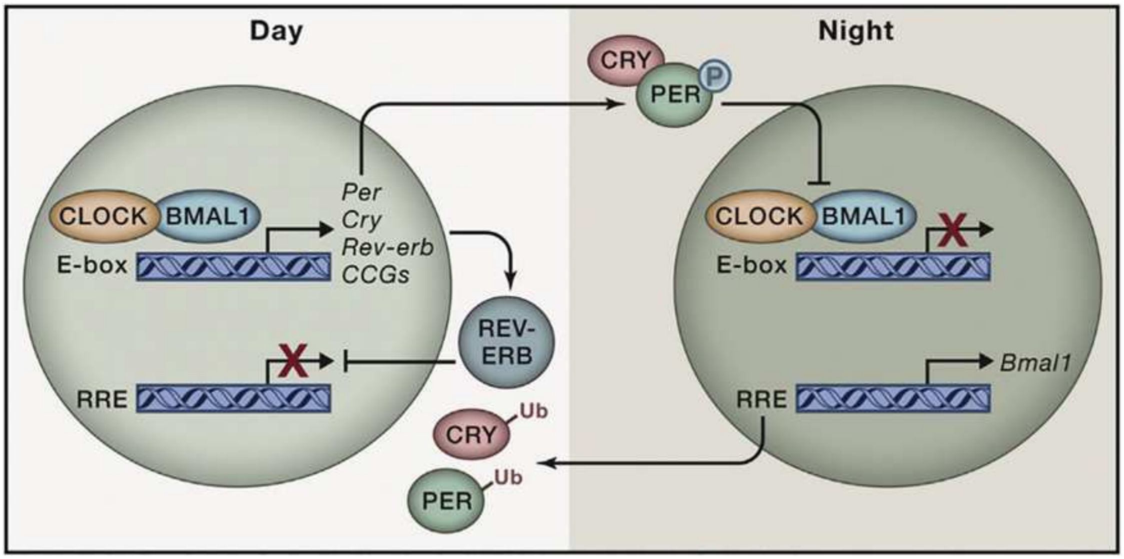

Fig. 3.3 The machinery of the intracellular circadian clock, present in almost all mammalian cells. *CLOCK* and *BMAL1* are transcriptional activators that dimerize to activate core clock genes (*CCGs*) including the expression of *Per, Cry* and *Rev-erb*. Levels of PER and CRY proteins increase to maximal levels during the night, where they themselves form dimer complexes, translocate to the cell nucleus, and suppress *CLOCK:BMAL1* transcription. Post-translational modification of *PER* and *CRY* proteins facilitate their degradation, a necessary step to start a new circadian cycle. In a second loop, high concentrations of *REV-ERB* proteins during the day inhibit *Bmal1* transcription, while at night, low levels of *REV-ERB* allow transcription to take place. (From Asher G, Sassone-Corsi P. Time for Food: the intimate interplay between nutrition, metabolism, and the circadian clock. *Cell.* 2015;161:84–92.)

In contrast to the daily circadian rhythm, the *ultradian* rhythm of glucocorticoids is characterized by the pulsatile secretion of hormone every 60 to 90 minutes, as determined in studies of both rodent animals[18] and humans.[20,28] There is no evidence of any rhythms of this frequency in the hypothalamus, and hypotheses from mathematical modeling predict that ultradian oscillations in ACTH and cortisol secretion occur at a subhypothalamic level as a consequence of dynamic interactions between positive feedforward from pituitary ACTH on the adrenal and negative feedback generated by adrenal cortical glucocorticoids[29] on pituitary corticotrophs. These predictions have been validated in rodent models where ultradian oscillations of ACTH and corticosterone (the dominant glucocorticoid in rodents) persist even under conditions of constant CRH infusion,[30] thus demonstrating that pulsatile CRH secretion is not required for the ultradian rhythm of glucocorticoids.

Glucocorticoid Pulsatility

The importance of ultradian glucocorticoid secretion has for the most part been investigated in animal experiments. These have shown that expression of genes and gene transcripts in the rodent liver[31,32] and brain[33,34] are differentially influenced by the altering patterns of exposure to the principal glucocorticoid in rodents, corticosterone. In contrast to rats exposed to constant levels of glucocorticoid, ultradian pulses induce cyclical glucocorticoid receptor–mediated gene transcription, or "gene pulsing."[31] In humans, evidence for the biological consequence of patterns of glucocorticoid exposure is hinted at by differences in HPA axis pulsatility in adults with depression[35] or sleep apnea[36] and following major cardiac surgery.[37,38] Specific evidence of the potential importance of glucocorticoid pulsatility on normal cognitive function has emerged from recent experiments in healthy adults. In a protocol in which endogenous cortisol production was suppressed, only participants who received pulsatile replacement were able to perform well in cognitively demanding tasks, compared with those participants who received standard oral or continuous infusion replacement regimens.[39]

Rhythms in Endocrine Disease

Pathological rhythmicity driven by the secretion of hormones from tumors is the hallmark of many endocrine diseases. For example, high-frequency blood sampling in patients with pituitary adenomas reveals pulsatility of growth hormone, prolactin and cortisol secretion rather than simply tonic hypersecretion.[40] Disorganized and irregular but pulsatile secretion of glucocorticoid has been identified in patients with both Cushing disease[41] and adrenal Cushing syndrome.[42] A diurnal rhythm with superimposed ultradian pulsatility also characterizes the rhythm of aldosterone secretion in health and in primary aldosteronism, differentiated by higher basal release and secretion irregularity in the disease condition.[43]

Limitations of Single Timepoint Assessments

Given that hormonal processes are dynamic, occasional assessment of single hormones at restricted timepoints provides incomplete, and potentially misleading, information. Single-timepoint measurements also fail to capture the significant and important metabolic and hormonal changes that occur during sleep. The major fluxes of both melatonin and cortisol occur during this time, and the sleep period is typically the only part of the day in which the fasting state can be observed without interference with or from any daily activities.

CELL CLOCKS

The intrinsic cell clock machinery present both in neurons of the SCN and in peripheral tissues consists of transcriptional-translational feedback loops that oscillate with a period of approximately 24 hours (Fig 3.3). The principal loop is made up of two transcription activators: brain and muscle ARNTL-like protein 1 (BMAL1) and circadian locomotor output cycles kaput (CLOCK). The BMAL1/CLOCK dimer complex activates numerous so-called "clock-controlled genes," as well as inducing transcription of *period* (*PER*) and *cryptochrome* (*CRY*). Increasing levels of PER and CRY proteins act via negative feedback to inhibit CLOCK and BMAL transcription, PER and CRY are degraded, and the cycle begins once more.[44] In addition to these core components, feedback is also regulated by a number of posttranslational mechanisms, including phosphorylation and glycosylation of clock proteins.[45] Studies in rodents have demonstrated that malfunction of clock genes leads to alterations of circadian period,[46] while deactivating mutations of *Per2/Cry1* result in the complete dysregulation of the circadian rhythms of ACTH, corticosterone, and clock gene expression in mice.[26] In humans, a hereditary delayed sleep phase disorder has been associated with gain-of-function mutation in the *CRY1* gene.[47]

KEY POINTS

- Cells in the brain and in peripheral tissues contain clock machinery consisting of transcriptional-translational feedback loops that oscillate with a period of approximately 24 hours.

THE SLEEP-WAKE CYCLE

Sleep can be defined as a reversible, temporary state of altered consciousness, characterized by reduced responsiveness, altered muscle activity, and changes in metabolism.[48] Sleep is a highly complex process involving multiple interacting systems ranging from gene expression to whole-body physiological regulation, and, despite its regular occurrence and the considerable time that it occupies in our lifetime, there remains much that is not understood (for reviews see Dijk & Landholt[3] and Carskadon & Dement[49]).

Sleep Regulation

The regulation of sleep in humans has been described by a two-part model consisting of a *homeostatic* process, represented by sleep debt, and a *circadian* process that is controlled by the SCN circadian pacemaker.[50] In the model, homeostatic sleep pressure increases with increasing time awake and abates again during sleep. The sleep period oscillates with a circadian period that is normally entrained to the light cycle of day and night.[50] In animal experiments, lesions to the SCN do not disrupt sleep homeostasis,[51] indicating that the two processes are distinct. Uncoupling the sleep-wake cycle from the circadian rhythm in humans can be achieved using *forced desynchrony* protocols in which day length is gradually extended to 28 hours, a period beyond which the circadian pacemaker can entrain. This allows researchers to separate the individual influences of the circadian and homeostatic processes on sleep,[52] as well as the ability to assess the "free-running" periods of circadian rhythms independent of the sleep-wake cycle.[53,54]

Sleep Stages

Laboratory studies of human sleep typically measure multiple physiological variables, which are standardized into a protocol known as *polysomnography*.[55] Measurement of the electroencephalogram (EEG) simultaneously with eye movement and muscle tone represents the core features by which stages of sleep can be defined. Broadly, sleep can be divided into cyclical periods of rapid eye movement (REM) sleep that occur every 90 to 120 minutes on the background of periods of non-REM (NREM) sleep, each defined by distinct patterns of EEG and muscle activity.[56] The transition between wakefulness and the onset of sleep is classified as stage N1 sleep. A sleep period that contains large amounts of N1 indicates frequent arousals including, for example, those caused by sleep apnea.[56] Stage N2 constitutes the majority of NREM sleep, whereas deep sleep (N3) is more predominant in the earlier part of the night. REM sleep accounts for approximately 25% of sleep time,[56] becomes dominant in last third of the night,[49] and is closely correlated with the circadian rhythm of core body temperature.[57]

MELATONIN AS THE BIOLOGICAL MAKER OF THE NIGHT

In controlled, dimly lit conditions, melatonin begins to rise in the evening, before habitual bed time, and remains elevated during the night, before falling to very low levels during the day.[58] Profiles of melatonin vary between individuals and across gender, age, and chronotype[9,59-62] but are generally stable within an individual. This means that measurement of melatonin is considered a robust and reliable marker of circadian phase.[9] Light is the most potent synchronizer of the circadian clock, and light exposure has a profound effect on the secretion of melatonin. Bright light exposure in the morning leads to a phase advance (earlier melatonin onset), whereas light exposure in the evening delays or suppresses melatonin secretion.[63-66]

Measurement of circulating plasma melatonin remains the gold standard for assessment of the endogenous circadian phase in humans.[9] Full profiling of melatonin typically requires admission to a specialist research unit and drawing of multiple blood tests. The onset of melatonin in ambulatory settings is usually estimated by obtaining a partial profile in saliva during the hours leading up to habitual bed time,[9] which is less invasive than blood sampling, but requires active participation from the participant (physical collection of samples, altering light and body position if collecting in dim light conditions).[67]

Although there is unequivocal evidence that exposure to artificial light influences melatonin rhythms,[68-71] there is as yet no strong mechanistic link between this disruption and any specific pathology. In a case-control study of nurses, those with the lowest excretion of urinary melatonin metabolites were significantly more likely to develop type 2 diabetes than those with the highest levels.[72] In a study of 21 healthy female volunteers, 5 mg of exogenous melatonin resulted in impaired glucose tolerance at both morning and evening timepoints, when glucose was measured acutely after dose administration.[73] Further, melatonin receptor mutations have been linked with an increased risk of impaired glucose tolerance and type 2 diabetes in gene-wide association and prospective studies,[74-76] but in an analysis of data from more than 189,000 participants in the UK Biobank, the presence of the mutation was not associated with increased risk of diabetes in shift workers.[77] Untangling the complex relationships between evening bright light–induced melatonin suppression with associated behaviors such as late meals, natural interindividual variation in chronotype and light sensitivity, and any effect on sleep duration or quality remains a significant challenge.

CONSEQUENCES OF RHYTHM DISTURBANCE ON METABOLIC HEALTH

Robust evidence of the importance of coordinated rhythms in the maintenance of health comes from the study of clock-absent animal models—disabling mutations in core clock genes results in loss of not only behavioral rhythmicity but also the development of abnormal metabolic phenotypes that include obesity, impaired glucose metabolism, lipid disorders, and reduced lifespan.[78,79] In the wild-type condition, factors that normally function to synchronize and entrain daily rhythms, such as hormones, light, and food timing, can become instead "desynchronizers"—that is, exert harmful phase shifting effects—when presented at the wrong time of day, or without coordination.

KEY POINTS

- Factors that act to desynchronize rhythms include mistiming of sleep and meals, exposure to bright light during normal periods of sleep and rest, and the pathological changes in rhythmicity that occur in endocrine diseases.

Sleep Mistiming and Human Health

There is increasing evidence that misalignment of sleep is associated with metabolic dysfunction. Epidemiological studies have linked late chronotype (evening preference) with increased risk of multiple comorbidities and all-cause mortality.[80] Short sleep duration has been associated with an increased risk of diabetes and obesity,[80,81] and sleep fragmentation with impaired glucose tolerance.[82] Following 7 days of partial sleep deprivation, transcriptome analysis of plasma obtained from 26 adult volunteers found that over 700 genes were either up- or downregulated, including a significant reduction in the number of genes with circadian expression. These included *PER*, *CRY*, and *CLOCK*, as well as upregulation of genes associated with immune and stress responses.[83]

Shift workers are a particularly vulnerable group. Successive night shifts are associated with an accumulation of sleep debt,[87] and during recovery sleep quality may still be affected for many days after completing night shift work.[87]

A metaanalysis of 26 studies involving over 300,000 participants found that shift work was associated with a significant increased risk of overweight and obesity,[84] and a review of 38 metaanalyses and 24 systematic reviews additionally found links with shift work and increased risk of type 2 diabetes, coronary artery disease, stroke, and cancer.[85] A systematic review of 33 observational studies found that shift workers overall consumed a less healthy diet, were less regular with meal timing, and were more likely to consume food at night.[86]

Jet Lag and Social Jet Lag

Rapid shifts in time zone associated with air travel frequently results in a collection of symptoms commonly known as “jet lag,” a syndrome that has been formally acknowledged as a sleep disorder.[88] Jet lag occurs as a direct consequence of acute misalignment of internal timing rhythms with day/night cycles. Symptoms include difficulty initiating and/or maintaining sleep, excessive sleepiness, altered alertness and performance, and somatic symptoms of altered gastrointestinal function.[88]

Direction of travel influences the effect on the circadian system, with eastward flight, which requires a phase advance of the circadian timing system, being generally more difficult to adapt to than westward travel, which requires a phase delay.[89] Phase adjustment may be hastened by optimizing the timing of bright daylight exposure in the new time zone,[90] and a systematic review of randomized trials concluded that there is good evidence to recommend the use of melatonin supplementation to reduce or prevent the symptoms of jet lag, where travel occurs over at least five time zones, especially in an eastward direction.[89] Where the duration of a trip is short (<3 days) it may be best to maintain a “home-based” sleep pattern rather than attempt to adapt to the new time zone.[91]

“Social jet lag” describes the discrepancy in sleep time that may occur between work and free days.[92] Societal pressures around work and education schedules may conflict with the naturally selected sleep patterns of many individuals, leading to an accumulation of sleep debt. The amount of social jet lag can be quantified by calculating the difference between the midpoint of sleep on work days compared with nonwork days.[92] Thus, people with an evening chronotype (who prefer later bed and wake up times) may be disproportionately affected by the requirement to adhere to a social timetable that requires rising early in the morning for work or school. Large-scale surveys in European populations suggest that two-thirds of working-age people suffer from at least 1 hour of social jet lag, and one-third from at least 2 hours.[93] There is an increasing body of evidence that, like shift work, social jet lag is associated with potentially unhealthy lifestyle choices[94] and other health problems, including smoking,[92] obesity,[95] and metabolic disturbance.[96,97]

NOVEL TECHNOLOGY FOR THE STUDY OF BIOLOGICAL RHYTHMS

Accurate and confident diagnosis of endocrine disease is important and remains a challenge, especially for diseases such as Cushing syndrome and primary aldosteronism. To make progress in understanding the significance of rhythmic changes in human endocrinology and metabolism, more data need to be collected at high resolution, including during undisturbed sleep. In-laboratory protocols involving the sampling of blood are the gold standard, but are typically laborious, invasive, and expensive. Further, the circumstances in which data are captured in laboratory settings are unlikely to reflect the life conditions that patients inhabit when they present for assessment at the clinic.

Novel technology in the form of continuous ambulatory microdialysis presents an opportunity to study the daily rhythms of hormones and metabolites at high frequency and within a framework of normal life. Clinical microdialysis involves the placement of a semipermeable membrane (probe) into the tissue of interest, and then perfusion of the probe at a slow flow rate, producing a microdialysate containing dialyzed substances of interest. Coupling microdialysis with a portable collection device developed by the Lightman group,[98] frequent (20-minute) automated sampling in subcutaneous tissue has become possible over a full 24-hour period, during which the participant is able to continue normal activities.[99,100] Work using the prototype device has so far demonstrated that circadian profiles of free cortisol are not only detectable in subcutaneous fluid,[98] but remain robust over time and correlate with total plasma concentrations.[99] With the emergence of mass spectrometry as an analytical method,[101] simultaneous measurement of multiple analytes has now become achievable. For example, using this approach it has been possible for the first time to demonstrate the presence and rhythmicity of tissue free melatonin, measured simultaneously with cortisol and its metabolite cortisone (Fig. 3.4). A major multicenter clinical trial of the technology to measure daily rhythms of multiple tissue adrenal steroids in health and in endocrine conditions (ULTRADIAN, https://clinicaltrials.gov/ct2/show/NCT02934399), with the aim of providing clinical benefit through the provision of informative dynamic data without the need for blood sampling or hospital admission, has recently completed recruitment (Fig. 3.5).

KEY POINTS

- Capturing the dynamics of daily rhythms may provide an opportunity to improve the understanding of disease processes, as well as facilitating faster and more accurate diagnosis of endocrine conditions.

SUMMARY

As humans have evolved to live in a constantly changing environment, rhythmicity has become an intrinsic feature of our physiology. Rhythms of different periods and amplitude coordinate and synchronize with one another to create systems of dynamic equilibrium that can adapt to the unique circumstances of the individual. Key rhythms in humans include the diurnal circadian rhythm of glucocorticoids, which also exhibit ultradian pulsatility, and the circadian rhythm of melatonin, a marker of the biological night.

Aside from these two hormones, almost all hormone and metabolic processes are rhythmic, coordinated by cellular clocks and feedback/feedforward loops that optimize physiological functions for the appropriate time of day. Endocrine and metabolic disease occurs when the timing or oscillation of these rhythms becomes pathological or desynchronized.

CONCLUSIONS

Although the importance of rhythms is become increasingly recognized, there remains a major knowledge gap around the mechanisms

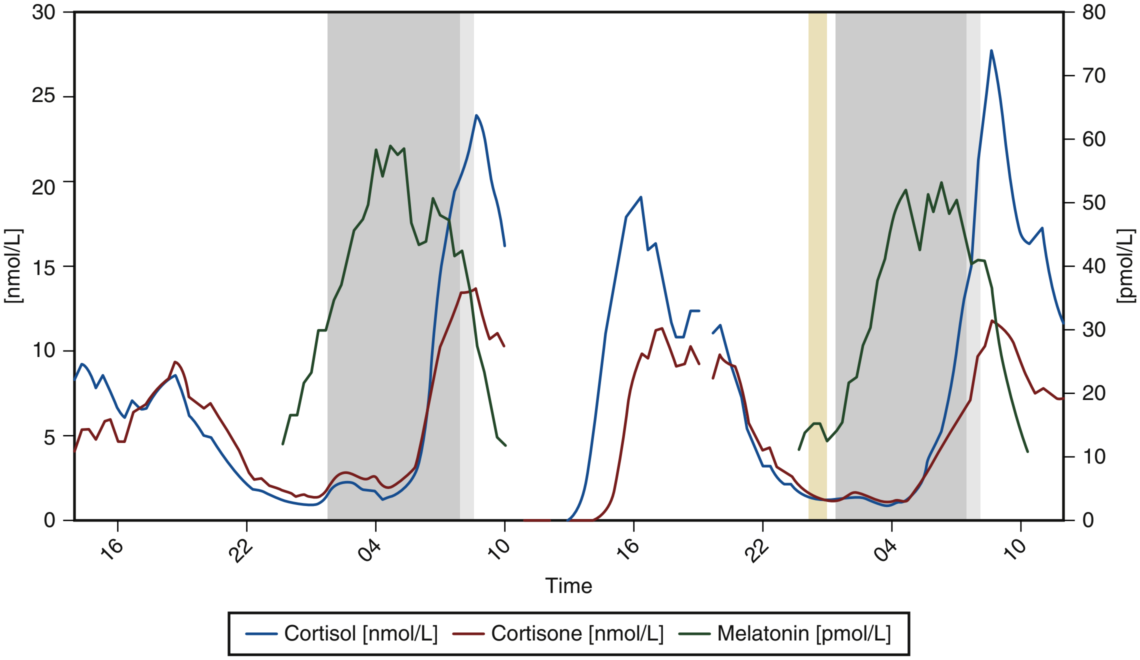

Fig. 3.4 Free tissue cortisol, cortisone, and melatonin profiles collected over 2 consecutive days using ambulatory microdialysis technology. In this illustrative example from a healthy male volunteer, samples were collected during normal living conditions in which the participant was free to choose ambient light conditions and sleep timing. As in the plasma example (Fig. 3.1), diurnal rhythms in cortisol *(blue)* and cortisone *(red)* can clearly be observed, with nadir levels during sleep *(dark grey-shaded area)* and peaks anticipating habitual rising times *(light grey)*. Deliberate exposure to bright blue–spectrum light on the second night of sampling *(yellow shaded area)* is here associated with temporary suppression of melatonin and a delay reaching peak night-time levels. (Source: Author's own unpublished data.)

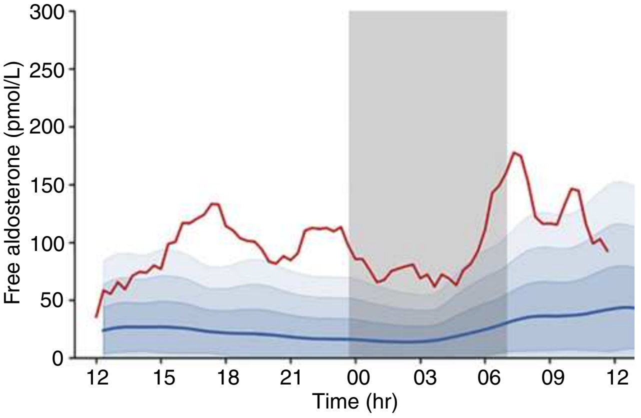

Fig. 3.5 **Example profile of the ultradian secretion of tissue free aldosterone in primary aldosteronism.** Free aldosterone *(red)* was measured over 24 hours in abdominal subcutaneous tissue using ambulatory microdialysis technology in a young adult undergoing investigation for hypertension. Mean aldosterone concentrations in 268 healthy adults *(blue, standard deviation in blue-shaded areas)* and the participant's sleep period *(grey)* are shown for reference. Adrenal vein sampling later confirmed unilateral overproduction of aldosterone. (Source: Unpublished data from the ULTRADIAN study [https://clinicaltrials.gov/ct2/show/NCT02934399), kindly provided by Dr. Eder Zavala, University of Birmingham.)

by which rhythm disturbance results in disease. Further studies in clinical populations are needed, and data from ambulatory high-frequency tissue sampling may provide new insights into the understanding of rhythm dynamics, as well as the mechanisms by which disruption results in endocrine and metabolic disease.

HISTORY

Nonphysiological hyperprolactinemia is the most prevalent hypothalamopituitary dysfunction and its main cause is prolactinomas. These are the most common pituitary tumors with a prevalence of 500 cases per million inhabitants.[1] These tumors are classified as microadenomas (diameter <10 mm) or macroadenomas (≥10 mm) and can be enclosed, expansive or invasive.[2] Prolactinomas are more common in women, especially microprolactinomas. Prolactin-secreting pituitary carcinomas are exceedingly rare.[3] As hyperprolactinemia usually is associated with menstrual disturbances, anovulation, and sexual impairment and prolactinomas commonly affect people under their 40s, these tumors are an important cause of infertility. Other causes of hyperprolactinemia, as physiologic and drug-induced, must be ruled out to diagnose prolactinoma properly. Also, awareness of laboratory and imaging pitfalls can avoid incorrect diagnosis and treatment.[4] New therapeutic approaches such as temozolomide for aggressive/resistant prolactinomas have been used.[5]

"If a woman is neither pregnant nor has given birth, and produces milk, her menstruation has stopped." This sentence, attributed to Hippocrates (*Aphorisms,* Section 5, #39), shows that the association between menstrual disturbances and inappropriate milk secretion has been known since ancient times. It was only in the twentieth century, however, that such disturbances were associated with hypersecretion of a pituitary hormone. In 1928, Striker and Grueter[6] identified a pituitary factor that was able to induce milk secretion in rabbits. Early in the eighteenth century, Hunter discovered that "pigeon's milk," a substance secreted by male and female pigeons to feed the young pigeon, is secreted by the crop, and according to Hunter, "the crop behaves like the udder of mammalian females regarding uterine gestation." In 1933, Riddle and colleagues[7] identified the stimulatory effect of a pituitary hormone on pigeons' crop growth and differentiation, which also controlled milk secretion in mammals, and called it *prolactin* (PRL). The pigeon's crop model later was used for the PRL bioassay. Coincidentally, the association of amenorrhea, infertility, and galactorrhea were described better around the 1930s.

The existence of a human PRL, distinct from growth hormone (GH), remained controversial, however, until the development of a specific radioimmunoassay for PRL in the early 1970s,[8] when it was shown that all the above-mentioned syndromes were linked to elevated serum PRL levels. The development of pituitary microsurgery and, later on, high-resolution imaging techniques showed that most of the cases with a normal sella on plain x-rays, described as nontumoral, were small pituitary tumors (microadenomas). There are many other causes of hyperprolactinemia that must be differentiated from prolactinomas so that a correct therapeutic approach can be instituted.

Cloning the genes encoding PRL and its receptor brought a better understanding of hyperprolactinemia physiology and pathophysiology.[9,10] More recently, kisspeptin has been shown to be involved in hypogonadism as a result of hyperprolactinemia,[11] pointing to future approaches for hyperprolactinemia-induced hypogonadism.[12]

KEY POINTS

- Prolactinomas usually are sporadic and benign pituitary tumors. Microprolactinomas frequently occur among women between 30 and 40 years old and mainly impact gonadal status and fertility, whereas macroprolactinomas are more common in men, and tumor mass effects such as headache and visual impairment are important issues.

EPIDEMIOLOGY

Hyperprolactinemia is the most prevalent hypothalamopituitary dysfunction, with prolactinomas being the main cause. Although prolactinomas represent nearly 50% of adenohypophyseal tumors in autopsy series, they correspond roughly to 25% of surgically-removed pituitary adenomas,[13] which is probably best explained by the excellent results of medical treatment of prolactinomas with dopaminergic agonists. Their prevalence is estimated at 500 cases per million individuals in the United States, with an incidence of 27 cases/million/year.[13] Nevertheless, prolactinoma standardized incidence rates could be higher, up 5.41 cases/100,000/year.[1] Vroonen et al. reviewed prolactinoma frequency in seven recent epidemiologic studies, confirming that prolactinoma is the most common pituitary adenoma, accounting for between 40% to 66% of tumors (Table 4.1).[1]

Prolactinomas present a sex bias, occurring ten times more frequently in females compared with males until the age of 50 years, when the proportion is 1:1.[14] Microprolactinomas (diameter <10 mm) represent about 60% of PRL-secreting adenomas and are more common in women than in men (20:1), whereas macroadenomas have roughly the same prevalence in both genders.[14] There are no sex-related differences in autopsy series. Prolactinomas occur at all ages, with the diagnosis made predominantly in the 20s and 30s in both sexes.[13] They are the most frequent pituitary adenomas encountered in childhood and adolescence.[13] Prolactinomas represent the minority of pituitary tumors diagnosed after age 65 years[13]; however, their diagnosis may be underestimated, and macroadenomas were much more frequent than microadenomas when prolactinomas were diagnosed after the menopause.[15] Prolactinomas are the most prevalent pituitary adenoma in the multiple endocrine neoplasia type 1 (MEN1) syndrome.[13] Isolated familial prolactinomas have been described[16] (see also Chapter 14). Also, sporadic prolactinomas in young patients and familial pituitary tumors are related to germline mutations in the *aryl hydrocarbon receptor interacting protein* (AIP).[17] Prolactinomas can also be associated with pheochromocytomas/paragangliomas in patients harboring germline mutations in the succinate dehydrogenase complex subunits or mutations/intragenic deletions in *MAX*.[18] Pituitary carcinoma, defined by the presence of metastasis, is a vey rare entity. Recently, 72 cases were reviewed in the literature, with those with PRL secretion being the second most frequent type (23%).[3] (See also Chapter 15.)

KEY POINTS

- Hyperprolactinemia is the most common neuroendocrinology disturbance, occurring in 70% of women with irregular menses and galactorrhea.

TABLE 4.1 Epidemiological Studies of the Prevalence of Pituitary Adenomas and Prolactinomas (%)

	Country	Pituitary Adenoma Prevalence	Prolactinomas %
Daly et al., 2006	Belgium	1/1064	66.2
Fontana et al., 2009	Switzerland	1/1241	56.0
Fernandez et al., 2010	United Kingdom	1/1289	57.0
Raappana et al., 2010	Finland	1/1471	51.0
Gruppetta et al., 2013	Malta	1/1321	47.0

Reproduced with the permission of S. Karger AG, Basel. From Vroonen L, Daly A, F, Beckers A: Epidemiology and Management Challenges in Prolactinomas. *Neuroendocrinology* 2019;109:20-27. doi: 10.1159/000497746.

PATHOGENESIS

Similar to other pituitary adenomas, prolactinomas are probably monoclonal in origin. To date, the exact mechanisms leading to the development of lactotroph adenomas are not well established. Drug treatment is effective in 80% to 90% of cases; therefore, the minority of patients undergo surgical treatment, which means that the tumor samples available for research studies are not representative of prolactinomas in general. Among the genes that contain candidate pathological mutations are the pituitary tumor transforming gene (*PTTG*) and the heparin-binding secretory transforming gene (*HST*), both of which induce angiogenesis through fibroblast growth factors (FGF-2 and FGF-4). Estrogens seem to play a pivotal role in these mechanisms, because estrogen-modulating drugs (e.g., tamoxifen and raloxifene) and an antiestrogen drug inhibit PTTG expression in prolactinomas *in vitro* and prolactinoma growth *in vivo*. Reduction in the expression of the leukemia inhibitory factor and nerve growth factor and overexpression of bone morphogenetic protein 4 and the high-mobility group A2 (*HMGA2*) gene are among other events that may potentially be involved in prolactinoma tumorigenesis.[19]

A decrease in dopaminergic inhibition seems to play a role, at least a permissive one, in prolactinoma development. Several studies have shown the development of prolactinomas in mice with D2 receptor knockout, with this phenotype being more severe and developing more quickly in female animals and in animals treated with estrogens.[20] To date, no "natural" mutations have been found in the gene encoding the D2 receptor.[21] $PRLr^{-/-}$ mice exhibited more intense hyperprolactinemia and larger tumors than did age-matched $Drd2^{-/-}$ mice, and there were cumulative effects in compound homozygous mutant male mice. This fact suggests that PRL inhibits lactotrophs not only by the activation of hypothalamic dopamine neurons, but also directly within the pituitary in a dopamine-independent fashion.

Polymorphisms in tumor suppressor genes (genes that regulate cell cycle and receptor growth factors) have already been described, as those coding for TGF-beta type II receptor[22] and DR2.[23]

Prolactinomas associated with MEN1 present inactivating mutations characterized by loss of heterozygosity at locus 11q13 and mutations in the gene encoding menin. It is generally claimed that these prolactinomas are larger and more aggressive than their sporadic counterparts.[13] The recently described inactivating mutations in the gene encoding AIP, located on chromosome 11q13.3, are frequently found in isolated familial pituitary adenomas (mainly somatotropinomas, but also prolactinomas),[17] but rarely in sporadic pituitary tumors.[24]

PATHOLOGY

The terms *microadenoma* and *macroadenoma,* coined by Hardy,[25] denote pituitary adenomas measuring less or more than 1 cm, respectively. These adenomas are generally enclosed within a pseudocapsule, but also can be invasive. Macroprolactinomas also can be enclosed but usually expand to the optic chiasmal region or invade local structures such as the cavernous sinus or the sellar floor and sphenoid sinus. Prolactinomas can be classified according to pathology subtypes as sparsely-granulated lactotroph adenomas, densely-granulated lactotroph adenomas, and acidophilic stem cell adenomas, with the last two subtypes being more aggressive.[26] The sparsely-granulated lactotroph is the most common type, composed of medium-sized cells with chromophobic to slightly eosinophilic cytoplasm and a central, oval nucleus. Microcalcifications are commonly seen in lactotroph adenomas, and amyloid-like substance, forming small hyaline bodies, can also be found.[27]

Acidophilic stem cell and sparsely-granulated lactotroph adenomas are well characterized by immunohistochemistry[27] (Fig. 4.1).

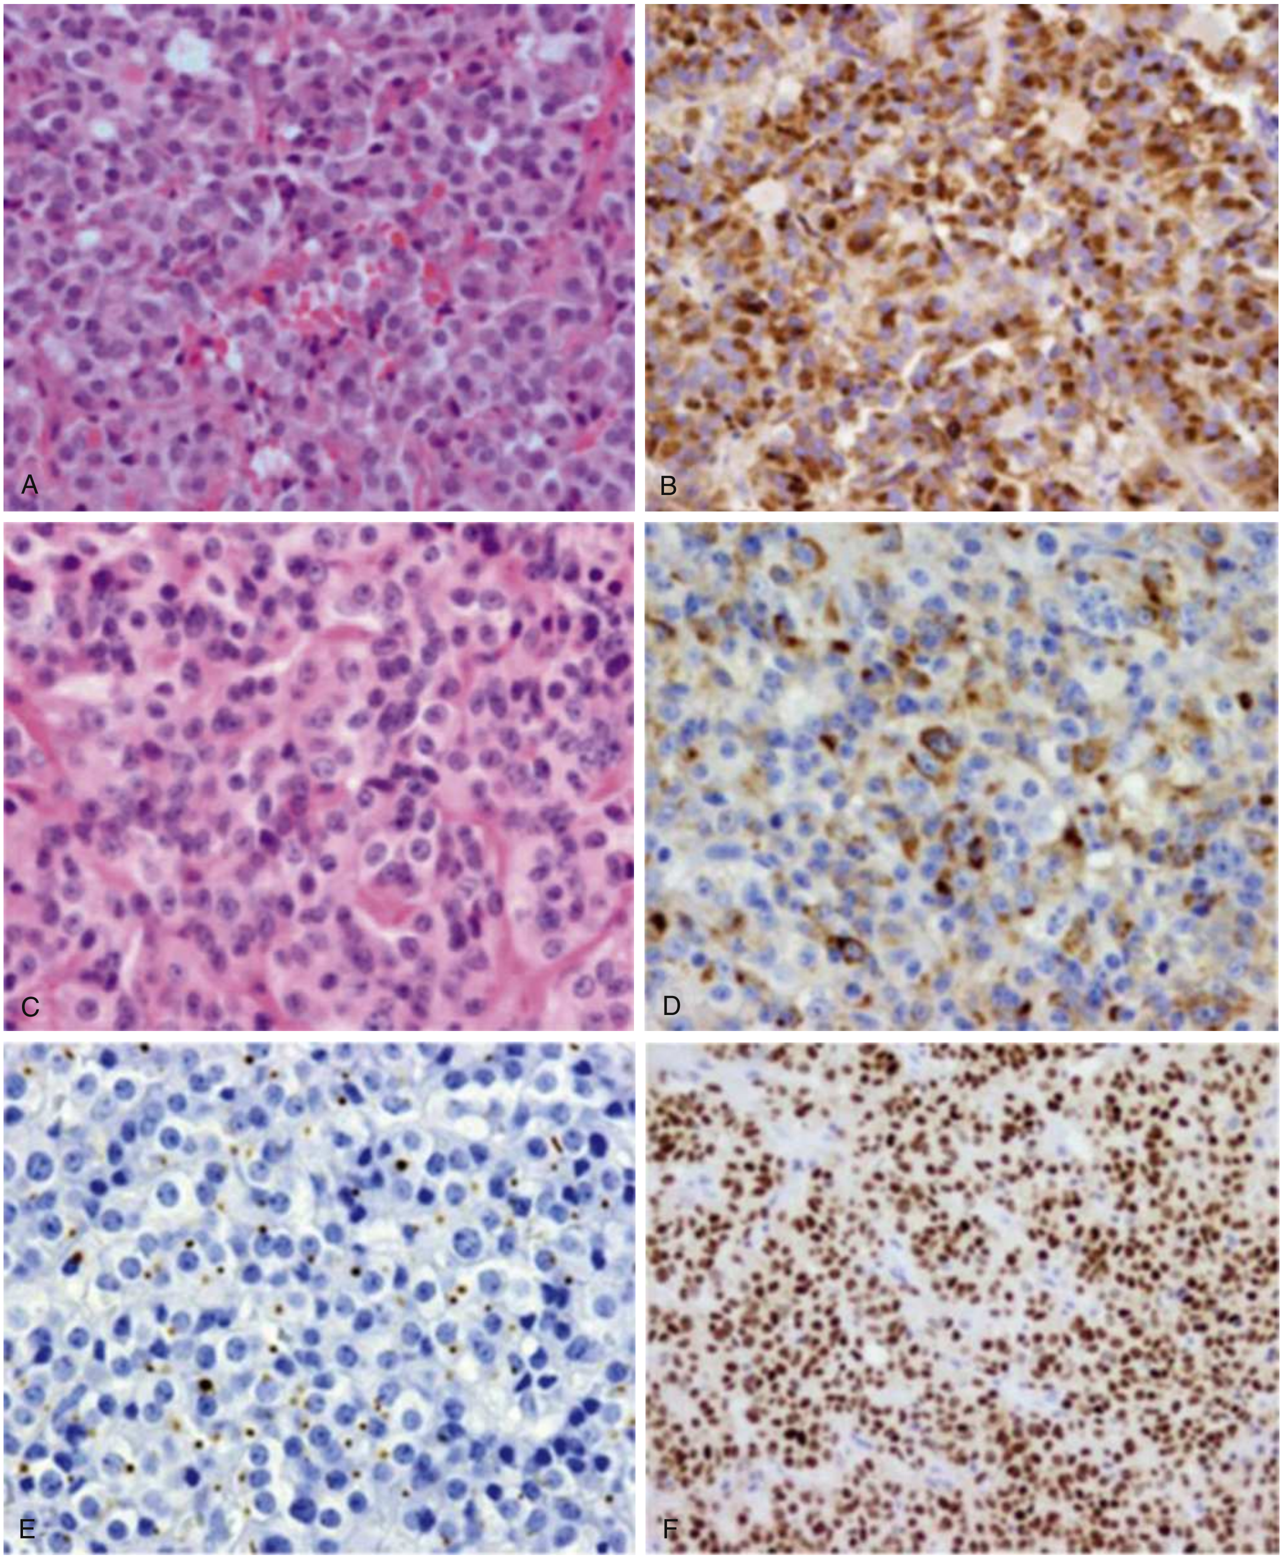

Fig. 4.1 **A,** Sparsely granulated lactotroph adenomas are composed of slightly acidophilic or chromophobic cells containing a central nucleus with well-dispersed chromatin (hematoxylin and eosin stain (H&E). **B,** Immunohistochemistry (IHC) for prolactin (PRL) in sparsely granulated lactotroph adenomas is characteristic, with paranuclear location in a dot-like pattern (Golgi-like pattern) (PRL-IHC). **C,** Acidophilic stem cell adenomas are characterized by cells with acidophilic cytoplasm with focal oncocytic changes (H&E). **D,** Immunoexpression of PRL is variable in the tumor and in the cells in acidophilic stem cells adenomas (PRL-IHC). **E,** Cytokeratin immunostaining highlights small fibrous bodies that are not present in either sparsely or densely granulated lactotroph adenomas (cytokeratin-IHC). **F,** All pathological variants of prolactinomas express the acidophilic lineage transcription factor Pit-1, here exemplified in an acidophilic stem cell adenoma (Pit-1–IHC). (From Lopes MBS. Pathology of prolactinomas: any predictive value? *Pituitary*. 2020;23:3–8.)

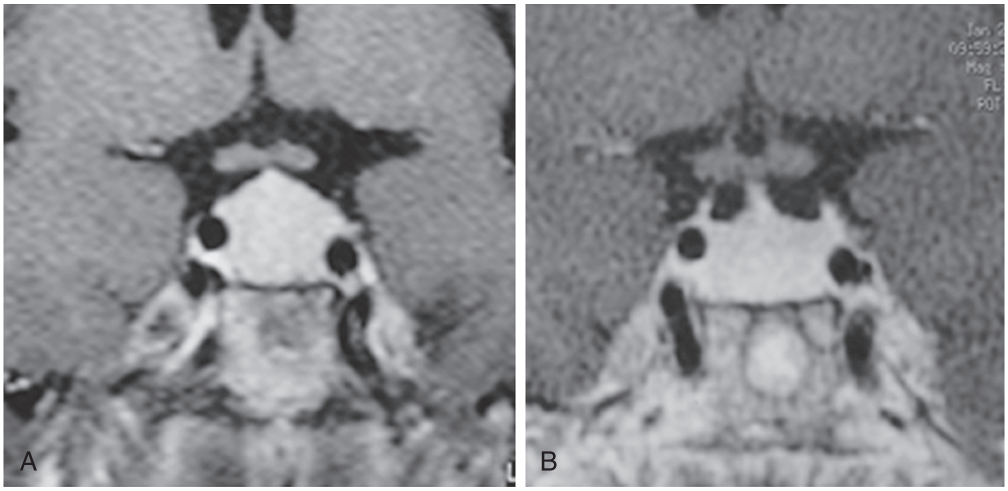

Fig. 4.2 Magnetic resonance imaging (gadolinium-enhanced Tl-weighted coronal views) of a 41-year-old woman with primary hypothyroidism **A**, before and **B**, after 1 month on levothyroxine replacement therapy. (From Bronstein MD. Problems in the differential diagnosis of the hyperprolactinemic patient. Clinical Endocrinology Update 2003. Miami: Endocrine Society; 2003:241–247.)

Nontumoral Lesions Associated With Hyperprolactinemia

Many nontumoral conditions can be mistaken for prolactinomas. Thyrotroph hyperplasia is associated with primary hypothyroidism as a result of loss of feedback (Fig. 4.2).[28] The correct diagnosis is important, because this condition regresses with thyroid hormone replacement.[28] Idiopathic lactotroph hyperplasia is a rare cause of hyperprolactinemia that can be mistaken for an expanding macroprolactinoma. The pituitary mass shape can help in the differential diagnosis. Inflammatory lesions such as lymphocytic hypophysitis (occurring mainly during pregnancy and the puerperium) and sarcoidosis can be misdiagnosed as a lactotroph adenoma.[29]

Pituitary Prolactin-Secreting Carcinomas

Pituitary PRL-secreting carcinomas are exceedingly rare tumors that exhibit morphologic features indistinguishable from those of PRL-secreting adenomas (see also Chapter 15). In addition to local invasiveness, distant intracranial and extracranial metastases in the nervous system and visceral metastases are necessary for the diagnosis of malignancy. Regarding intracranial lesions, sometimes it is difficult to distinguish between contiguity of an invasive prolactinoma and true metastasis from a PRL-secreting carcinoma.[3]

DIFFERENTIAL DIAGNOSIS OF HYPERPROLACTINEMIA

The main causes of hyperprolactinemia are listed in Table 4.2.

Physiologic Hyperprolactinemia

Throughout pregnancy, owing to estrogen-induced hypertrophy and hyperplasia of lactotrophs, the size of a normal pituitary increases up to 136%, and serum PRL levels progressively increase. A recent study including 378 healthy pregnant women showed the following median PRL serum levels in each trimester: 79.0, 144.6, and 306.6 ng/mL in the first, second, and third trimester, respectively.[30] Serum PRL levels decline quickly after delivery but remain slightly increased in nursing women for several months, especially with breastfeeding.

Because exercise and nonspecific stress are physiologic causes of hyperprolactinemia, there is a concern that the stress-induced PRL increase could lead to hormone elevation during venipuncture, and a period of rest before drawing blood is recommended if those conditions are suspected.[31]

TABLE 4.2 Causes of Hyperprolactinemia

Physiologic
- Pregnancy and puerperium
- Neonatal period
- Physical activity
- Stress

Drug-Induced
- Dopamine receptor blockers
  - Sulpiride
  - Chlorpromazine
  - Haloperidol
  - Risperidone
  - Metoclopramide
  - Domperidone
- Serotonin reuptake inhibitors
- Cimetidine
- Tricyclic antidepressants
- Verapamil
- Methyldopa
- Protease inhibitors

Pathologic
- Pituitary disease
  - Prolactinomas
  - Acromegaly
  - Cushing disease
  - Nelson syndrome
  - Lymphocytic hypophysitis
  - "Empty sella" syndrome
- Hypothalamic disease and hypothalamus/pituitary disconnection
  - Nonfunctioning pituitary adenomas
  - Meningiomas
  - Dysgerminomas
  - Craniopharyngiomas
  - Inflammatory/granulomatous
  - Sarcoidosis
  - Histiocytosis
  - Stalk section
  - Vascular
  - Actinic
- Neurogenic
  - Chest wall lesions
  - Spinal cord lesions
- Miscellaneous
  - Primary hypothyroidism
  - Adrenal insufficiency
  - Uremia
  - Cirrhosis
  - Paraneoplastic
  - Idiopathic

KEY POINTS
- Pregnancy, drugs, hypothyroidism, and uremia should be ruled out before diagnosing prolactinomas.

Pharmacologic Hyperprolactinemia

Among medications that increase serum PRL, dopamine receptor blockers are the most potent. Neuroleptics (e.g., sulpiride,

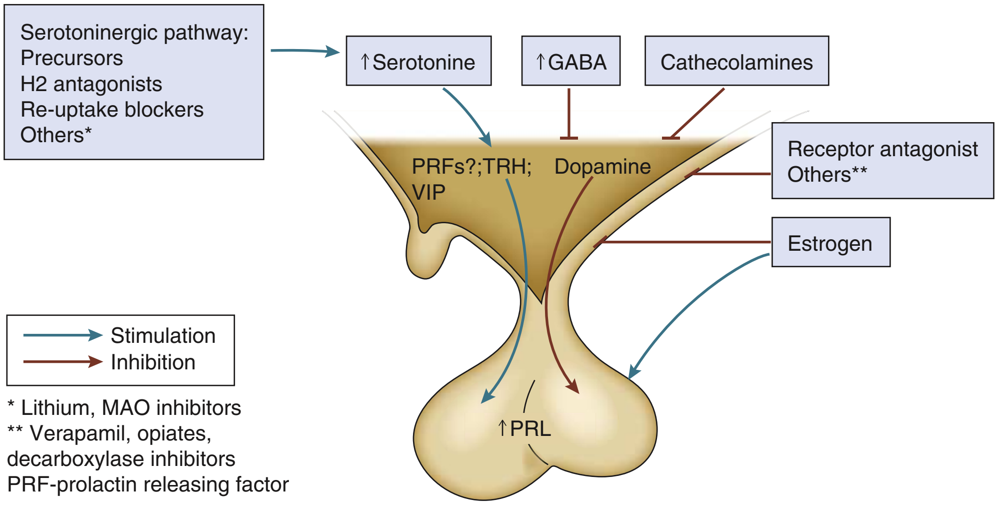

Fig. 4.3 Mechanisms related to drug-induced hyperprolactinemia. *GABA,* Gamma aminobutyric acid; *MAO,* monoamine oxidase; *PRF,* prolactin-releasing factor; *PRL, prolactin; TRH,* thyrotropin-releasing hormone; *VIP,* vasoactive intestinal polypeptide.

haloperidol, chlorpromazine, risperidone) and antiemetic drugs (e.g., metoclopramide, domperidone) can elevate serum PRL to levels that usually are detected with prolactinomas. Serotoninergic and antihistaminergic drugs are less potent than antidopaminergic medications. The calcium channel blocker verapamil elevates serum PRL levels, probably by decreasing central dopamine generation, and possibly through N-type calcium channels. It was shown that protease inhibitors used for the treatment of acquired immunodeficiency syndrome can cause hyperprolactinemia, but the mechanism is unknown. A detailed inquiry about drug use is mandatory for all hyperprolactinemic patients.[32]

Hyperprolactinemia may occur in patients on opioids, although its prevalence and the impact of dose, route, and type of drug have not been clearly established. Fig. 4.3 summarizes mechanisms related to drug-induced hyperprolactinemia.[33]

The Endocrine Society guidelines recommend treating hypogonadism induced by hyperprolactinemia related to antipsychotic drugs with hormonal replacement, if there is no contraindication.[31] Nevertheless, the association of psychiatric drugs inducing hyperprolactinemia and the use of dopamine agonists (DAs) has been reported. Such combined treatment must only be used with the agreement of the psychiatrist and with close follow-up.[34]

Pathologic Hyperprolactinemia

Hyperprolactinemia is present in about 40% of acromegalic patients as a result of GH/PRL cosecretion by the same or by different tumor cells, or secondary to hypothalamus-pituitary disconnection. Thus, the Endocrine Society recommends screening all prolactinoma patients for GH hypersecretion at the time of diagnosis.[31] As some studies have pointed to the development of acromegaly in about 4% of prolactinoma patients during long-term follow-up under DA therapy, regular monitoring of insulin-like growth factor–1 (IGF-1) levels is suggested by some authors.[35]

Hyperprolactinemia secondary to impaired hypothalamiotuberoinfundibular dopamine secretion or to stalk or even intrapituitary disconnection can be caused by tumors, inflammatory diseases, or trauma. In these cases, PRL is produced by the normal lactotrophs and rarely exceeds 150 μg/L. The differential diagnosis of macroprolactinomas is mainly clinical and is seen in nonfunctioning pituitary adenomas ("pseudoprolactinomas") and, to a lesser extent, with craniopharyngiomas.[36] Other tumoral lesions, such as meningiomas and chordomas, and nontumoral conditions, such as "empty sella" syndrome and even intrasellar aneurysms, can be associated with hyperprolactinemia, however.[37] The differential diagnosis between macroprolactinomas and pseudoprolactinomas is crucial regarding primary treatment, which is medical for macroprolactinomas and surgical for pseudoprolactinomas. Patients with nonfunctioning tumors treated with DAs were previously considered to have resistant macroprolactinomas, owing to the absence of tumor shrinkage even with the (obvious) PRL decrease to very low or undetectable levels (Fig. 4.4).[38] A clue to differentiate pseudoprolactinomas from true prolactinomas is the dramatic early PRL decrease with a low dose of DA.

Primary hypothyroidism can be associated with hyperprolactinemia, presumably as a result of high thyrotropin-releasing hormone levels that stimulate PRL release and presumably reduce PRL metabolic clearance. Thyrotroph hyperplasia may occur, leading to pituitary enlargement mimicking a pituitary adenoma (see Fig. 4.2). Cushing disease and adrenal insufficiency can be associated with hyperprolactinemia, which also can be present in Nelson syndrome.

Uremia can be associated with hyperprolactinemia, mainly in patients with end-stage renal disease. The mechanism probably is related to reduced PRL clearance and to a presumably reduced dopaminergic tonus. Hyperprolactinemia is present in up to 20% of patients with liver cirrhosis, probably because of an unbalanced estrogen-to-androgen ratio and to an altered dopaminergic tone. Nipple manipulation and chest-wall lesions, such as herpes zoster and surgical scars, may increase serum PRL via stimulation of neuron pathways going through the spinal cord.[29] Ectopic production of PRL has rarely been described.[39] Finally, when all the abovementioned causes are ruled out, hyperprolactinemia is considered idiopathic or functional.[40] It is likely, however, that most patients with this condition may harbor tiny microprolactinomas undetected by imaging. De Bellis et al.[41] pointed out the presence of antipituitary antibodies in patients with idiopathic hyperprolactinemia, suggesting an autoimmune etiology for a subset of cases. Also, Newey et al. reported three sisters with hyperprolactinemia attributed to a heterozygous loss-of-function mutation in the PRL receptor gene, resulting in prolactin insensitivity.[42]

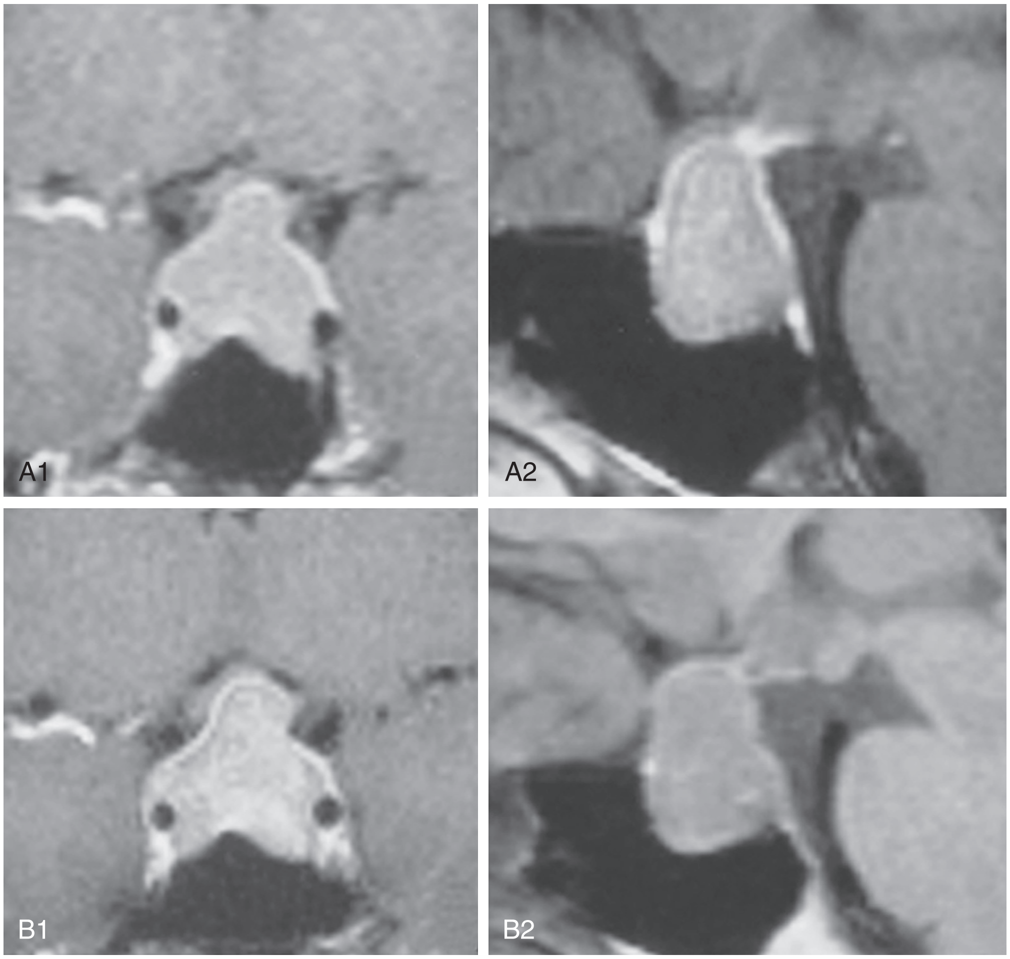

Fig. 4.4 Magnetic resonance imaging of a 41-year-old woman with a nonfunctioning pituitary adenoma and serum prolactin level of 51 ng/mL before (**A1,** coronal view; **A2,** sagittal view) and during the twelfth month of cabergoline treatment (**B1,** coronal view; **B2,** sagittal view). No tumor shrinkage was observed, despite serum prolactin decrease to 1.2 ng/mL. (From Bronstein MD. Problems in the differential diagnosis of the hyperprolactinemic patient. Clinical Endocrinology Update 2003. Miami: Endocrine Society; 2003:241–247.)

KEY POINTS

- Hyperprolactinemia causes hypogonadotrophic hypogonadism, especially because of impairment in gonadotropin-releasing hormone secretion and pulsatility, via kisspeptine. The gold standard treatment for prolactinoma is dopamine agonists, because of their efficacy in normalizing serum prolactin levels, restoring the gonadal axis, and reducing tumor dimensions in 80% to 90% of cases. Neurosurgery, radiotherapy, and chemotherapy can be indicated in partially/completely resistant tumors.

DIAGNOSIS OF PROLACTINOMAS

Clinical Features

Hyperprolactinemia and its impact on the gonadotropic axis are the hallmark of microprolactinomas and macroprolactinomas and their clinical manifestations. Macroprolactinomas also may cause neurologic and visual disturbances and impairment of other pituitary functions owing to the tumor mass effect (Table 4.3).[43] Loss of visual fields and impairment of visual acuity are the main ophthalmologic manifestations. Headache is the most common neurologic presentation; this is typically attributed to dural stretch or cavernous sinus invasion, and less frequently to the clinical symptoms of pituitary apoplexy. Other rare presentations of invasive macroprolactinomas

are hydrocephalus, neuropsychiatric manifestations, and otoneurologic manifestations.[44]

Women generally present with a correlation between the degree of serum PRL elevation and gonadal impairment, ranging from a short luteal phase to amenorrhea (Fig. 4.5).[45] The main mechanism involved in hypogonadism related to hyperprolactinemia is the suppression of the pulsatile secretion of gonadotropin-releasing hormone, via kisspeptin.[11] Its administration reverses gonadal status and restores fertility in animals and in hyperprolactinemic women.[12]

In addition to menstrual disturbances, hyperprolactinemic women complain of loss of libido, vaginal dryness, dyspareunia, and psychological distress.[46] Similar to other disorders associated with hypogonadism, osteoporosis is a frequent finding in women with hyperprolactinemia/prolactinomas, mainly in prolactinomas with longstanding hypogonadism. Although a direct effect of PRL on bone has been considered, there is evidence that hyperprolactinemia is not a risk factor in itself for the development of osteoporosis, with the associated hypoestrogenism being the major determinant.[47]

Galactorrhea is a frequent finding in women with hyperprolactinemia, but it can be absent, mainly in patients with macroprolactinomas associated with severe hypogonadism. Breast examination, if not adequate, also may fail to disclose mild galactorrhea. These facts may explain the discrepancy among series, which show a prevalence of galactorrhea ranging from 30% to 84%.[48] Galactorrhea also may occur in normoprolactinemic women. A study including 235 patients with galactorrhea associated with diverse conditions showed that serum PRL was normal in 86% of women with idiopathic galactorrhea without amenorrhea.[49] The mechanism is unknown, and is attributed to different causes such as mammary hypersensitivity to PRL or "occult" transient hyperprolactinemia.

Hyperprolactinemia in men is predominantly associated with macroprolactinomas. The main clinical manifestations are hypogonadism, which is usually severe, along with loss of libido and reduced body hair growth, visual impairment, and headache.[50] Testosterone replacement without serum PRL normalization seldom restores libido, an observation that points to a direct effect of PRL on sexual behavior, as previously suggested by animal models.[51] Galactorrhea is far less frequent in men than in women with prolactinomas. However, when present in men harboring pituitary tumors, it strongly suggests the presence of a prolactinoma.[52] Osteoporosis is also present in hyperprolactinemic men.[47]

Although the prevalence of prolactinomas in both genders is higher in the second and third decades of life, prolactinomas can occur in the elderly and in younger individuals.[53,54] The predominance of larger tumors in children and adolescents points to molecular mechanisms influencing proliferation rather than the time course of the disease influencing the progression of prolactinoma size and invasiveness.

Laboratory Evaluation

Except in cases where venipuncture induced significant stress, a single determination of high serum PRL level confirms hyperprolactinemia.[31] Ruling out other causes of hyperprolactinemia, the diagnosis of prolactinoma can be established. Microprolactinomas usually present PRL levels of 100 to 200 ng/mL, although values that are only two times the upper limit of the normal range can also be found (normal range <24–30 ng/mL).[55] Macroprolactinomas are usually associated with PRL values above 250 ng/mL, and giant prolactinomas with levels higher than 1000 ng/mL.[31,56] Mainly in macroprolactinomas, the assessment of other pituitary functions is mandatory. IGF-1 levels must be monitored either to verify GH deficiency or to identify the rare cases of prolactinomas that progress with PRL/GH cosecretion.[57] As restoration of pituitary function may occur after adenoma removal by surgery or tumor shrinkage attained by medical therapy,[58] these assessments have to be repeated after such procedures to avoid unnecessary hormone replacement.

Concerning other causes of hyperprolactinemia, serum PRL levels rarely exceed 150 ng/mL in hypothalamo-pituitary disconnection, as lesions that mimic macroprolactinomas, especially nonfunctioning pituitary adenomas, generally exhibit serum PRL levels below this value (pseudoprolactinomas).[36] Nevertheless, a laboratory artefact may lead to an erroneous differential diagnosis between macroprolactinomas and pseudoprolactinomas: when serum PRL is evaluated by two-site immunometric assays, large amounts of antigen—PRL in this case—saturate both capture and signal antibodies, impairing their binding and causing serum PRL to be underestimated (the so-called high-dose "hook effect"). Patients bearing macroprolactinomas with extremely high serum PRL levels (generally >10,000 ng/mL, depending on the assay measuring range) may present with falsely lower levels, within the 30 to 150 ng/mL range, causing the patient to be misdiagnosed as harboring a nonfunctioning pituitary adenoma. To avoid unnecessarily performing surgery (which is the treatment of choice for nonfunctioning tumors), PRL assays with serum dilution or using two-step incubation are recommended in patients with macroadenomas who may harbor a prolactinoma.[59]

If such assays are not readily available, clinical clues pointing to prolactinomas are patient age younger than 50 years, presence of galactorrhea in male patients, and tumor shrinkage in response to treatment with DA drugs, as shown by rapid visual improvement in cases with chiasmal compression or rapid tumor reduction evidenced by magnetic resonance imaging (MRI).[52]

Another laboratory pitfall concerns the presence of high serum PRL levels in subjects with few or no symptoms related to PRL excess. Human PRL in the circulation manifests a marked size heterogeneity, with three forms (23, 50, and 150–170 kD) that are indistinguishable by routine assays. The 23-kD form (little PRL) is the most common form, but serum PRL can be elevated secondary to the presence of 150- to 170-kD aggregates with low biological activity (big-big PRL), leading to *macroprolactinemia.*[60] The presence of molecular aggregates with low biological activity, such as big-big PRL, should be suspected when high serum PRL levels are detected in patients with no or scarce signs and symptoms related to hyperprolactinemia.[4,61] As the gold standard assay, gel filtration chromatography, is costly and time-consuming, precipitation with polyethylene glycol is usually employed to rule out macroprolactinemia.[31] Macroprolactinemia is a common finding, occurring in 8% to 42% of all cases of hyperprolactinemia.[4]

Despite controversies concerning the biological activity of PRL aggregates,[62] most patients with macroprolactinemia and normal monomeric PRL levels[63] do not manifest clinical features related to hyperprolactinemia and do not need any treatment. To avoid unnecessary medical or surgical procedures, macroprolactin screening is mandatory when clinical features and serum PRL assay results are conflicting.

KEY POINTS

- Macroprolactinemia is a frequent laboratory finding and, when associated with normal monomeric values, is a benign condition, not needing specific treatment. Hook effect, which underestimates serum PRL levels, can be avoided with serum dilution and is important to consider in the differential diagnosis of prolactinomas.

Imaging

MRI is currently the gold-standard imaging method for diagnosis and treatment follow-up of micro- and macroprolactinomas. MRI is superior to computed tomography (CT) for tumor boundary delineation, especially regarding its associations with the optic chiasm and cavernous sinus (Figs. 4.6 and 4.7). Additionally, tumor consistency, presence of hemorrhage, and presence of cystic lesions are better shown by MRI. CT still has its place, as it can be used to assess bone erosion and calcification and may help surgical planning.[64] Although MRI is currently the most sensitive imaging method for microprolactinomas, tumors measuring less than 2 mm may remain undetected by this technique, supporting the concept that the so-called idiopathic hyperprolactinemia actually is related to tiny microprolactinomas.[40]

It should be stressed that pitfalls such as macroprolactinemia and pituitary incidentalomas may lead to an erroneous prolactinoma diagnosis, leading to unnecessary medical, or even surgical, procedures.[4] Fig. 4.8 shows a flow diagram for the diagnostic evaluation of hyperprolactinemia.

TREATMENT

Therapy for hyperprolactinemia/prolactinomas aims to reverse the symptoms caused by hormone hypersecretion and the neurologic and visual manifestations attributed to tumor mass effect. The ideal treatment must spare or even improve other pituitary dysfunctions if present.

Treatment of secondary hyperprolactinemia is intended to treat or remove the cause of the disorder, such as primary hypothyroidism, surgical removal of a nonfunctioning pituitary adenoma, and withdrawal of drugs such as risperidone, when possible, to bring serum PRL down to normal levels.[32,36]

Regarding prolactinoma treatment two powerful therapeutic advances came about almost simultaneously in the 1970s: the improvement of pituitary microsurgery[2] and the development of ergot derivatives with potent dopaminergic agonistic activity.[65] Additionally, radiation therapy, mainly carried out by stereotactic techniques, has a place, albeit restricted (Table 4.4). The therapeutic strategy must consider several aspects, such as the patient's clinical presentation, the differences in natural history between microadenomas and macroadenomas, the desire for pregnancy, and the patient's treatment preference, if applicable.

Medical Therapy

Bromocriptine. Bromocriptine (BRC), an ergot derivative, was the first DA used in clinical practice. BRC binds and stimulates the seven–membrane-spanning domain dopamine D2 receptors in normal and in adenomatous lactotrope cells, inducing activation of the G_i receptor (negatively coupled to adenylate cyclase), which ultimately inhibits PRL synthesis and secretion.

Pharmacokinetic studies with BRC show that, after a single oral dose of 2.5 mg, serum levels peak, and maximal suppressive action

occurs between 1 and 3 hours. The drug has a relatively short mean elimination half-life (~6.2 hours) and generally is administered twice a day, although there are data indicating the efficacy of once-daily administration.[65]

BRC treatment results in serum PRL normalization and clinical improvement in most patients with hyperprolactinemia/prolactinomas. A compilation of 13 series from the literature, encompassing 286 women treated with BRC, showed PRL normalization and return of menses in 80% and 73 to 100% of cases, respectively.[66] Although less frequent, microprolactinoma in men also can be treated successfully with DAs. We have treated 11 men with microprolactinoma with DAs, and successfully achieved serum PRL and serum testosterone normalization in 73% and 86%, respectively.[67]

Because of the mass-reducing effect of BRC, this DA has also become a primary treatment for macroprolactinomas, as it can help avoid surgery, which is often noncurative.[68] Patients with giant prolactinomas (diameter >4 cm) also achieved disease control with primary BRC therapy.[69] In our series, serum PRL was normalized in 60% of women with macroprolactinomas (mean BRC dose 7 mg/day); 72% of these women had recovery of their menses. Menses also were restored in 44% of patients who remained hyperprolactinemic.[70] Regarding macroprolactinoma in men, serum PRL and testosterone levels normalized in 67% and 85%, respectively, of 66 patients bearing macroprolactinomas, showing that, in men also, the gonadotropic axis may normalize even when PRL is not fully normalized. We obtained 80% tumor reduction in primary-treated macroprolactinoma patients.[67] The time course of macroprolactinoma shrinkage is highly variable. Some patients experience a dramatic improvement of visual acuity 12 hours after BRC has been introduced, with tumor shrinkage documented within 1 week. Therefore, visual improvement usually occurs early after drug introduction and should suggest continuing medical treatment instead of performing surgery (Fig 4.9). In others, significant tumor reduction is observed only 1 year after medical therapy is started.[68]

Macroprolactinoma reexpansion during successful medical therapy, albeit uncommon, may occur, and can lead to visual impairment or headache recurrence.[71] Another rare situation is visual deterioration despite initial improvement, provoked by herniation of the optic chiasm secondary to tumor shrinkage. These two situations generally require surgical intervention, although drug reduction or discontinuation may repair the chiasmal herniation.[72] In addition, pituitary surgery is often needed for a third rare situation, cerebrospinal fluid (CSF) leakage, occurring in macroprolactinomas invading the sphenoid sinus in cases treated with DAs (Fig. 4.10). In such cases, the tumor shrinkage behaves as the cork removed from a wine bottle, opening a pathway for CSF flow. CSF leakage, which carries a risk of meningitis, often occurs shortly after the beginning of medical therapy but may manifest several months later.[73,74]

BRC-induced shrinkage of macroprolactinomas can restore other impaired anterior pituitary functions as a result of the restoration of hypothalamopituitary connection.[75] To avoid the maintenance of unnecessary hormonal replacement, pituitary function must be reassessed in patients with macroprolactinoma and previous hypopituitarism successfully treated with DAs.[75]

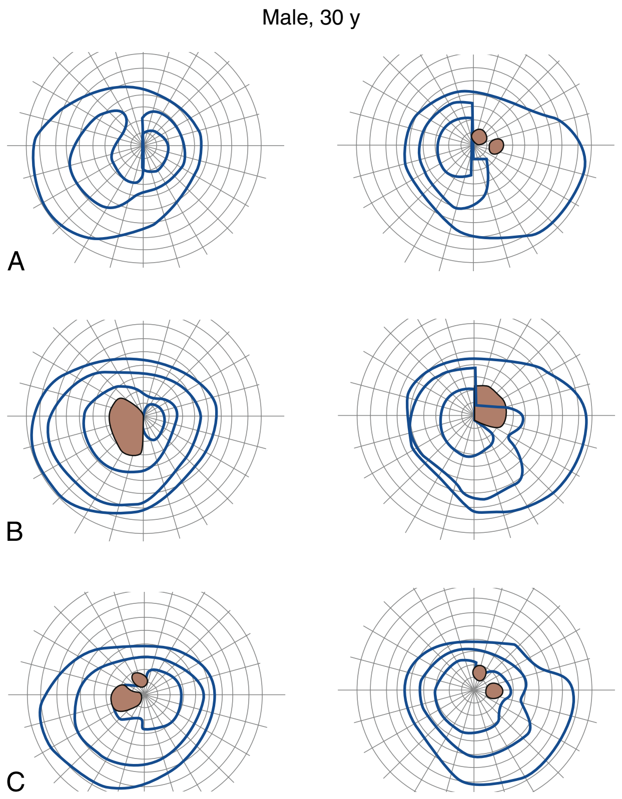

Fig. 4.9 Visual fields (Goldman perimetry) of a 30-year-old man harboring a macroprolactinoma. Impaired visual fields **A**, before treatment, **B**, showed amelioration 3 days after the beginning of bromocriptine treatment and **C**, were almost normalized after 28 days of drug therapy.

One of the drawbacks of medical therapy for prolactinomas is the need for long-term treatment. Nevertheless, a retrospective study from our group showed that 25.8% of 62 patients with microprolactinomas and 15.9% of 69 patients with macroprolactinomas treated with BRC for a median of 47 months continued to be normoprolactinemic for a median of 44 months after drug withdrawal.[76] There were no statistically significant differences regarding age, gender, BRC initial dose and duration of use, tumor size, pregnancy during treatment, or previous pituitary surgery or radiotherapy among patients who continued to be normoprolactinemic and patients who did not. Other reports from the literature point to a percentage of patients who remained normoprolactinemic after BRC cessation ranging from 6.6% to 50%.[76,77] The difference in long-term findings versus short-term findings may be explained by microscopic alterations of the lactotrope during BRC administration, suggesting a cytostatic effect related to short-term therapy and a cytocidal effect related to long-term treatment, which could explain the maintenance of normoprolactinemia after drug withdrawal.[78]

Another factor that may influence remission of prolactinomas is their natural history. A study including 25 women with untreated hyperprolactinemia (18 microadenomas, 7 macroadenomas) for a mean period of 11.3 years (mean initial PRL levels 225 ng/mL) showed that 7 of 22 patients with amenorrhea resumed menses spontaneously. Galactorrhea resolved completely in eight of 19 patients. Only one patient had a slight progression of sellar abnormality. At the reevaluation, mean PRL levels had decreased to 155 ng/mL.[79] Finally, there is evidence that women with hyperprolactinemia who experience the menopause have a significant chance of normalizing their PRL levels, pointing to the influence of estrogen.[80]

Among the problems associated with medical treatment of prolactinomas, drug side effects are the most prevalent. BRC is generally well tolerated at doses between 2.5 and 20 mg/day. The most frequent side effects are nausea, vomiting, orthostatic hypotension, and, to a lesser extent, nasal congestion, headache, constipation, and psychotic events, such as auditory hallucinations, delusional ideas, and mood changes. Care should be taken when prescribing the drug to psychiatric patients.[34] There have been isolated reports of leukopenia, hepatitis, headaches, and cardiac arrhythmias. Higher doses (20–140 mg daily), used for patients with Parkinson disease, may lead to pleural effusions, thickening, and parenchymal lung changes, as well as retroperitoneal fibrosis.[65]

The side effects of BRC can be minimized by starting therapy at 1.25 mg at bedtime after food intake and progressively increasing it

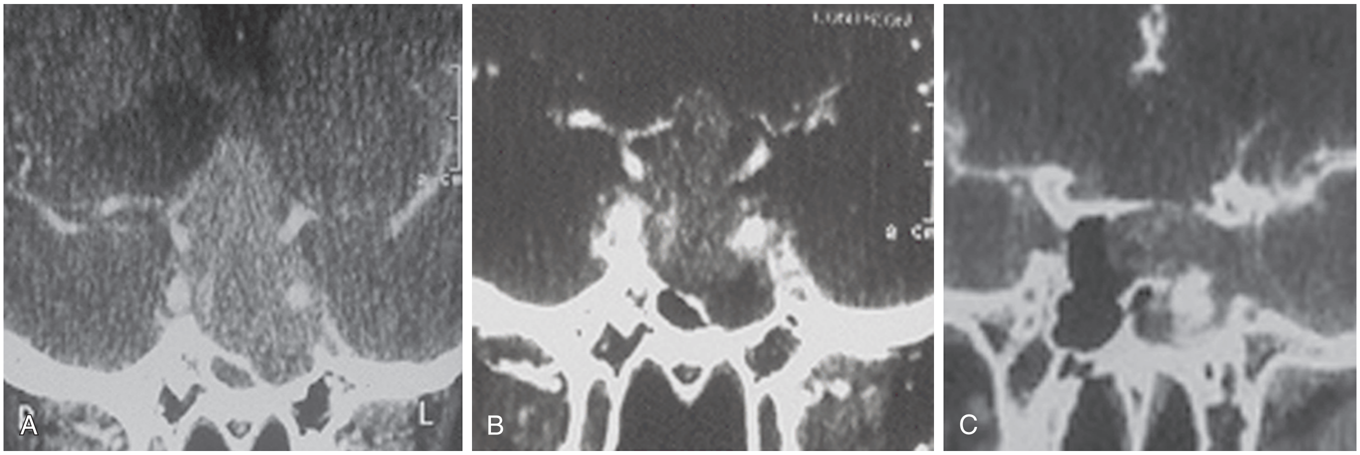

Fig. 4.10 Computed tomography (coronal views) of a man harboring a macroprolactinoma invading the sphenoid sinus **A**, before **B**, and 6 days after bromocriptine treatment, showing shrinkage mainly of the sphenoid sinus mass, **C**, with cerebrospinal fluid leakage confirmed by metrizamide injection.

to include 1.25 mg a day after breakfast and at bedtime, according to individual tolerance, until the therapeutic dose is achieved. When normoprolactinemia is obtained, the dose can be reduced in many cases.[77] A subset of patients remains intolerant, however, even when all such recommendations are followed.

An even more vexing problem in the medical treatment of prolactinomas is partial or complete lack of responsiveness to BRC. The definition of BRC resistance is arbitrary, with the failure of the drug in normalizing serum PRL levels or in reducing the tumor size using a dose equal to or greater than 15 mg/day for at least 3 months being the most currently accepted. According to this principle, about 10% of prolactinomas are resistant to BRC.[31] This criterion has limitations in clinical practice, however. Patients who are intolerant to BRC do not attain the dose established as the limit, and, although they are different conceptually, BRC intolerance and resistance overlap. Patients harboring expanding tumors with visual impairment should not be made to wait for 3 months without any improvement to confirm resistance. As previously mentioned, clinical amelioration and tumor reduction may be achieved even if serum PRL is still above the normal range.[70] Pragmatically, *BRC resistance* can be defined as the failure to obtain adequate clinical results in patients using the highest tolerable drug dose.

The mechanisms of prolactinoma BRC resistance have not yet been fully elucidated. *In vivo* and *in vitro* studies using radiolabeled dopamine antagonists as markers[81,82] or assessing D2 receptor expression by RT-PCR[83] show that dopamine D2 receptor density is reduced in resistant prolactinomas compared with tumors that are responsive to BRC. When the D2 receptor density in lactotrope cell membranes is extremely low, the DA drug may paradoxically lead to tumor growth.[82] The paucity of dopamine D2 receptors seems to be the main mechanism of BRC resistance in prolactinomas. Additionally, other events have been described such as a decreased ratio between the short and long isoforms of the dopamine D2 receptor, which are derived from alternative splicing,[84] and low filamin-A (cytoskeleton protein) expression.[85]

It is of note that some prolactinomas that are initially responsive to BRC become resistant during therapy. In such situations, especially in aggressive tumors, the diagnosis of the rare PRL-secreting carcinoma must be considered.[86]

Several other DA drugs have been employed for the treatment of hyperprolactinemia/prolactinomas. Many shows therapeutic efficacy, but two of them in particular merit detailed description, aiming mainly at overcoming intolerance and resistance to BRC.

Quinagolide. Quinagolide is a nonergot DA drug that has specific affinity for the dopamine D2 receptor. Its efficacy in normalizing serum PRL levels is similar to that of BRC, ranging from 45% to 100%, with most studies of patients with macroprolactinomas showing PRL normalization in between 58% and 75% of cases, paralleled by clinical improvement.[65] Quinagolide is administered once a day at doses ranging from 0.075 to 0.6 mg. Some studies point to better tolerance compared with BRC. Additionally, there is evidence that around 50% of patients with BRC-resistant prolactinomas attained normoprolactinemia when switched to quinagolide.[87] Such tumors were partially responsive to BRC, however, with the further decrease attributed to better patient tolerance and a higher affinity to the already reduced but still present dopamine D2 receptors. Tumor size evaluation in 105 patients showed more than 50% shrinkage and 25% to 50% reduction in tumor size in 48.1% and 20.2% of cases, respectively.[87] Quinagolide is commercially available only in Europe.

Cabergoline. Cabergoline (CAB) is a synthetic ergoline that shows high specificity and affinity for the dopamine D2 receptor. It is a potent and long-acting inhibitor of PRL secretion, with an elimination half-life ranging between 63 and 109 hours.[88] PRL-lowering effects occur rapidly within 3 hours and were evident after a single-dose administration at the end of follow up (21 days) in puerperal women and at 14 days in patients with hyperprolactinemia. This pharmacologic profile allows CAB to be administered once or twice a week in most patients, usually at a weekly dose of 0.5 to 2 mg. In our experience, normoprolactinemia was maintained in some patients taking one tablet (0.5 mg) of CAB every 10 days and even every 2 weeks. Many studies have shown the efficacy of CAB in normalizing serum PRL levels and reducing tumor size, with consequent improvement of clinical and visual manifestations (Fig. 4.11).

Many studies pointed to the better efficacy and tolerance of CAB compared with BRC.[89,90] In a multicenter Brazilian study, data collected from 388 patients (320 women and 68 men) bearing prolactinomas (220 microadenomas and 68 macroadenomas) showed that CAB was significantly more effective than BCR in inducing normoprolactinemia (81.9% vs. 67.1%), without any difference according to gender.[55] In a large, multicenter European comparative study including 459 women with hyperprolactinemic amenorrhea, 0.5 to 1 mg of CAB twice weekly was more effective than 2.5 to 5 mg of BRC twice daily in the treatment of hyperprolactinemic amenorrhea, restoring ovulatory cycles in 72% of women and normalizing plasma PRL levels in 83%, compared with 52% and 59% for BRC. Adverse effects were recorded in 68% of women taking CAB and 78% of women taking BRC, but only 3% discontinued CAB, whereas 12% stopped taking BRC because of drug intolerance.[89] Regarding CAB's effect on macroprolactinoma size, in a compilation of 12 series including 320 patients, 28.4% had a greater than 50% tumor shrinkage, 28.4% had a reduction between 25% and 50%, and 43% had less than 25% or no reduction at all.[87] Because many of these patients had been previously intolerant or resistant to other DAs, the poorer CAB results for macroprolactinoma shrinkage compared with other drugs may have been biased. This bias can be illustrated by a study showing that the rate of macroprolactinoma shrinkage greater than 80% after CAB treatment was higher in naive patients (92.3%) than in patients who were previously intolerant (42.1%), resistant (30.3%), or responsive (38.4%) to BRC or quinagolide.[91] As far as DA resistance in prolactinomas is concerned, some studies indicate that CAB normalized serum PRL levels in patients who were resistant to BRC and even to quinagolide. In two series dealing with BRC-treated prolactinomas without full PRL normalization, normoprolactinemia was achieved in 70% and 85% of patients when they were switched to CAB.[92,93] As previously pointed out (see section on quinagolide), such tumors did respond partially to BRC, however, and the additional decrease induced by CAB is probably related to its better tolerability and higher affinity to the reduced but still present dopamine D2 receptors. Consequently, severely resistant prolactinomas would not be expected to respond to any DA drug, and should be treated by different means.

Some studies emphasized the maintenance of normoprolactinemia in 23% of patients after CAB withdrawal for 12 months, on average. A long-term prospective study including 200 hyperprolactinemic patients showed that, 2 to 5 years after CAB cessation, normoprolactinemia still persisted in 76% of patients with "nontumoral" hyperprolactinemia, 70% of patients with microprolactinoma, and 65% of patients with macroprolactinoma.[94] These results suggest that CAB also compares favorably with BRC in terms of maintenance of normal PRL levels after drug withdrawal.[76]

In last decade, three metaanalyses evaluated normoprolactinemia after DA withdrawal (Table 4.5) and reported rates of 21% in 743 patients (BRC or CAB) in 2010,[95] 35% in 637 patients (only CAB) in 2015,[96] and 37% in more than 1100 patients in 2018 (BRC or CAB).[97]

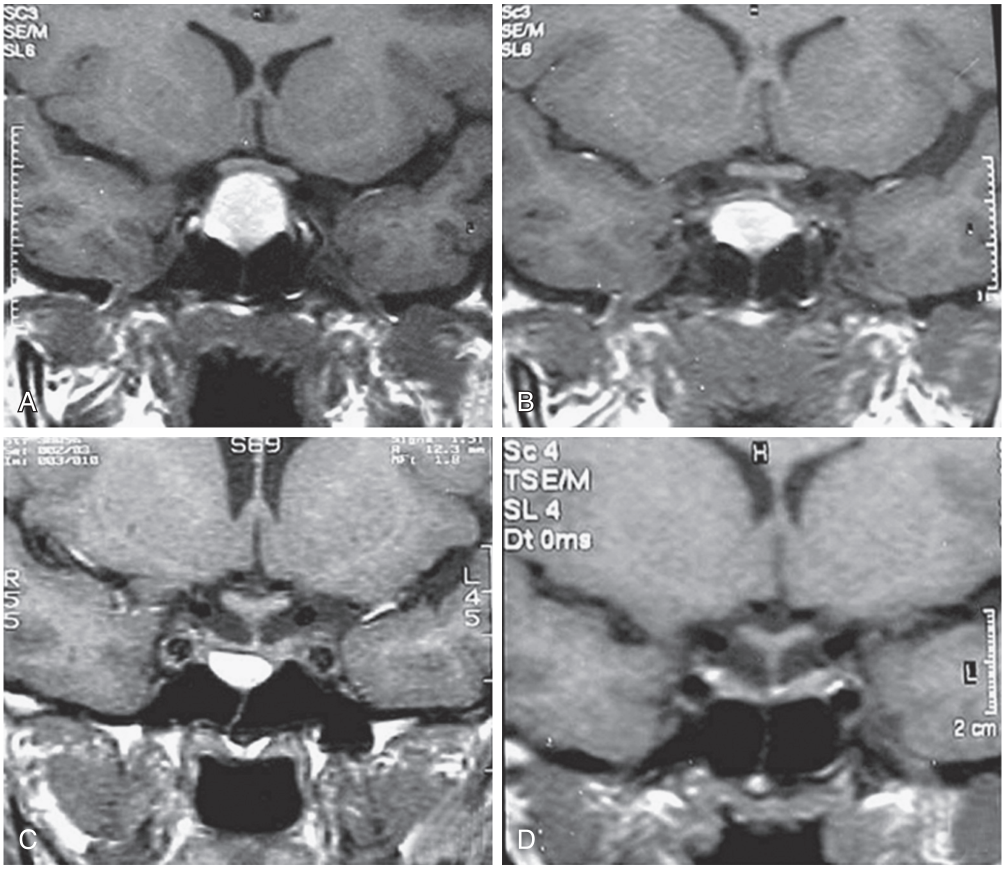

Fig. 4.11 Magnetic resonance imaging (T1-weighted with gadolinium enhancement) of a man bearing a large macroprolactinoma. **A,** Coronal view and **B,** sagittal view before treatment. **C,** Coronal view and **D,** sagittal view after 1 month of cabergoline treatment, showing significant tumor shrinkage that was paralleled by visual improvement.

TABLE 4.5 Summarized Data of Prolactinoma Remission From Metaanalyses

Xia et al., 2019	BRC/CAB	24	1106 727 MIC 306 MAC	36.6	CAB, length of treatment, normoprolactinemia, tumor reduction and low dose of CAB at withdrawal

BRC, Bromocriptine; *CAB,* cabergoline; *MAC,* macroadenoma; *MIC,* microadenoma.

These increasing remission rates could be associated with greater experience with CAB, a longer duration of treatment, and the implementation of better criteria for DA cessation.[98] In these different reviews, prognostic factors associated with remission were DA treatment at least for 2 years, normoprolactinemia, significant tumor volume reduction,[95,97] and a low maintenance dose of CAB.[96,97] Recurrence occurred especially in the first year after treatment cessation,[31] and a second attempt to withdraw CAB after 2 additional years of treatment is associated with lower remission rates.[99,100]

One concern regarding DA treatment is related to a potential risk of cardiac valvopathy, raised by two studies pointing to a high prevalence of cardiac valve dysfunction, compared with the general population, in patients treated for Parkinson disease with high doses of CAB (up to 3 mg/day), but not other DA drugs.[101] The supposed mechanism is related to an agonist effect on the $5HT_{2B}$ receptor, leading to inappropriate mitogenic stimulation on valve and chordae tendineae. Although this dose is much higher than that used for prolactinomas, the cumulative dose derived from the potential long-term use of CAB by patients harboring prolactinomas has raised concerns about the potentially harmful effects of this drug on the cardiac valves in this disease context.

Recently, a metaanalysis was performed that included 13 case-control studies with 836 hyperprolactinemic patients who received CAB for at least 6 months and excluded single case reports and previous metaanalyses. The authors found that more tricuspid regurgitation was observed in the CAB-treated patients compared with controls (although this was not associated with symptoms), but that there was no significant increase in any other valvulopathy.[102] The risk of clinically significant valvular disease (moderate tricuspid insufficiency) was observed only in one study, with a high mean CAB cumulative dose.[103] The Endocrine Society guideline on hyperprolactinemia treatment recommends transthoracic echocardiogram surveillance only for patients on CAB doses higher than 2 mg per week.[31] The British Committee recommends performance of a transthoracic echocardiogram before initiating DA treatment, and repeating annually if the CAB dose is higher than 2 mg weekly or at 5 years if a lower dose is used.[104] Our policy is to perform a transthoracic echocardiogram before and yearly during DA treatment, irrespective of the dose used.

A variety of psychiatric side effects as psychosis, mania, anxiety, depression, and, very importantly, impulse control disorders (ICDs) have been reported.[34]

ICD is defined as a failure to resist an impulse or the temptation to perform an act that is harmful to oneself or others, and can be manifested as pathological gambling, hypersexuality, binge eating, compulsive shopping, compulsive medication use, and punding (repetitive acts). This side effect is probably related to dopamine D3 receptor drug affinity, as observed with pramipexole and ropinirole in Parkinson disease.[105]

Five studies evaluated case series of patients with ICD harboring prolactinomas, pointing to hypersexuality in individuals taking DA.[34] Current smoking, alcohol use, and gambling history were associated with ICD.[106] These factors could be apparent from the medical history, and clinicians need to be aware of these potentially devastating side effects.

Despite such potential side effects, medical therapy seems to be the first option for prolactinoma therapy, being more effective than surgery, especially for macroprolactinomas,[107] including giant prolactinomas.[56] To date, CAB seems to be the first-choice drug for prolactinoma treatment in view of its remarkable tolerance, as well as its capacity to normalize serum PRL levels, reduce tumor size, and induce high rates of persisting normoprolactinemia after drug withdrawal.

Surgical Therapy

Pituitary surgery by the transsphenoidal approach was used at the beginning of the twentieth century and was reintroduced in the early 1960s, and greatly improved when the surgical microscope was introduced.[2,108] More recently, endonasal endoscopic surgery has become available. Compared to the classic transsphenoidal approach, endoscopic pituitary surgery seems to reduce the time of hospitalization, but a clear improvement in surgical results remains to be demonstrated.[109] Besides serum PRL normalization, this surgical modality aims at reducing or eliminating the mass effect of expanding macroadenomas, often leading to the resolution of neurologic and visual manifestations. The transcranial surgical approach is reserved solely for tumors with a predominant extrasellar location expanding out of the midline, when extended endoscopic transsphenoidal surgery is not indicated or available.[110]

Surgical success in normalizing serum PRL levels depends on the experience and ability of the surgeon and on the tumor size and invasiveness. Preoperative serum PRL levels, usually associated with tumor dimension and location, were found to be paramount in predicting surgical remission, being the only predictive factor in multivariate analysis in some reports.[107] Consequently, the best results were achieved in microprolactinomas with a preoperative serum PRL of 100 ng/mL or less.

A compilation of 50 published series showed that postsurgical serum PRL normalization was achieved in 73.7% of 2137 patients with microprolactinomas and 33.9% of 2226 patients with macroprolactinomas.[107] Comparison among the series is difficult, however, as many authors do not mention preoperative serum PRL levels, the tumor size, or the degree of invasiveness. The grade of clinical improvement in cured patients is high, mainly in smaller tumors. Menses and fertility restoration rates are high, and pregnancy rates range from 75% to 90% in different series. Some patients can achieve menstrual regulation and even become pregnant without full PRL normalization.[70,111] Sexual improvement in men is less likely to occur, probably owing to irreversible gonadotropic damage caused by the higher frequency of extrasellar and invasive prolactinomas compared with women. Nonetheless, pituitary function generally is preserved in intrasellar adenomas and is restored by the removal of suprasellar adenomas causing hypothalamopituitary disconnection.[111] In addition, neurologic and visual amelioration is frequently achieved after pituitary surgery.

Patient preference for surgical therapy should be considered in well-circumscribed micro and intrasellar macroprolactinomas, in a experienced and well-resourced pituitary center.[112] Also, in young women harboring microprolactinomas, surgery in experienced hands can be cost effective in tumor remission compared to long-term DA treatment.[113]

On the other hand, surgical debulking has been shown to improve further medical therapy in patients with prolactinomas that are partially resistant to DA.[114,115]

An important caveat of surgical treatment is prolactinoma recurrence. A literature compilation reported recurrence rates of 18.2% of 809 microprolactinomas and 22.8% of 465 macroprolactinomas.[107] In our series, the recurrence of hyperprolactinemia in surgically-cured patients was 27% for microprolactinomas and 17% for macroprolactinomas.[70] Median time to recurrence varied among the different surgical series, from 1 to 7 years.

Although the occurrence of relapses contributes to the decrease of long-term surgical cure rate of prolactinomas, many patients with recurrent hyperprolactinemia remain asymptomatic and have no evidence of tumor regrowth.[116] Relapse can be transient. From a cohort of 44 patients with surgically cured microprolactinomas, eight (18.2%) experienced recurrence and were followed up. Only two of the eight patients experienced permanent relapse.[117] Additional therapy is reserved only for patients with symptomatic recurrence.

Surgical treatment for prolactinomas is indicated for cases with persistent intolerance or hormonal or tumor resistance to DAs, pituitary apoplexy,[118] tumor growth during medical therapy,[71] CSF leakage attributed to DA-induced tumor shrinkage of invasive macroprolactinomas,[73,74] and (rarely) visual loss on medical therapy, secondary to optic chiasm herniation resulting from tumor retraction.[72] Additionally, surgery is an excellent alternative for patients harboring microprolactinomas, especially patients with serum PRL of 100 ng/mLor less, with poor compliance with medical therapy.[119] Table 4.6 summarizes the indications for in prolactinomas.

Intolerance/resistance to dopamine agonists
Apoplexy
Cerebrospinal fluid leakage owing to dopamine agonist-induced tumor shrinkage
Visual loss on medical therapy, secondary to optic chiasm herniation resulting from tumor retraction
Microprolactinoma and patient preference

Radiotherapy

The efficacy of conventional radiation therapy for prolactinomas is lower than that of medical or surgical treatment. Our results for 19 patients who underwent radiotherapy after medical/surgical failure showed that only three (16%) achieved serum PRL normalization 5, 6, and 15 years after the procedure.[70] A compilation from the literature shows serum PRL normalization in less than one third of patients 5 to 15 years after conventional radiotherapy, with hypopituitarism occurring in 5.5% to 93.3% of cases.[107] The prevalence is probably greater in reality, because many series underestimate GH deficiency in adults. Other complications associated with conventional radiotherapy include optic nerve lesions, neurologic dysfunctions, cerebrovascular disease, and the development of other intracranial tumors.

As conventional external beam radiotherapy (EBRT) can result in these significant complications, it has largely been replaced by stereotactic radiosurgery (SRS), mainly single-shot gamma knife "radiosurgery" (GKRS). According to the Clinical Practice Guidelines published by the European Society of Endocrinology,[5] GKRS is indicated for tumors with a maximal diameter less than 3 cm and a distance from the optic chiasm of at least 3 to 5 mm. Otherwise, fractionated EBRT is the better option. In addition, EBRT is preferred for tumors with irregular anatomy, including suprasellar or brainstem extension and diffuse local infiltration.[120]

In a compilation of 17 studies including 416 patients, the success rate of GKRS was reported to be 4.5% to 83%.[121] Different biochemical control criteria and different follow-up intervals probably explain this wide variation in the literature regarding remission and complication rates.

A recent multicenter study evaluated the role of SRS in prolactinomas, including 289 patients treated between 1997 and 2016 at 10 institutions: endocrine remission (normal PRL without DA) occurred in 28%, 41%, and 54% of patients at 3, 5, and 8 years, respectively, whereas endocrine control (PRL level ≤30 ng/mL on DA) was the more common endpoint, obtained in 63% of cases. Regarding complications, 25% presented a new hormone deficiency, 3% a new visual complication, and 5% tumor progression. A pretreatment PRL level of 270 ng/mL or less was a predictor of endocrine remission.[122] It is important to note that tumor growth after radiotherapy is a rare event,[123] and its occurrence in this study could be the result of selection bias because only patients with medically refractory or residual/recurrent tumors that were not amenable to resection were included.

Whether or not to maintain DA during radiotherapy is a controversial point. In three studies, the remission rate was low in patients on DA, whereas in another three studies, medical treatment did not influence the results.[121]

More data and increased follow-up time are required to assess the superiority of GKRS to conventional radiotherapy. In the authors' opinion, at present radiation therapy for prolactinomas should be reserved for cases with medical and surgical failures, especially for invasive tumors.

Therapeutic Advances and Perspectives

As a result of the efficacy of medical and surgical therapies, prolactinomas can be adequately controlled in most patients. A subset of patients who are resistant to DAs, especially patients harboring invasive macroadenomas who are not expected to be surgically cured, pose an important therapeutic problem. Radiotherapy use is generally limited, is efficacious only in the long term, and usually leads to hypopituitarism.

Many studies did not find tumor enlargement in patients with "idiopathic" hyperprolactinemia or microprolactinomas, before or after the menopause.[124,125] Sexual steroid replacement can be considered for patients for whom pregnancy is not a concern, and galactorrhea is not disturbing; these patients must then be followed carefully. Additionally, testosterone may be given to men harboring resistant microprolactinomas and even partially resistant macroprolactinomas, with PRL level monitoring and imaging. The introduction of an aromatase-inhibitor drug may be considered if there is evidence of tumor growth or a serum PRL increase.[126]

The use of clomiphene citrate as an alternative to testosterone therapy for men with hypogonadism has been described for patients both with and without normal PRL levels. The main advantage is fertility maintenance or restoration.[127]

Prolactinomas usually do not respond to somatostatin.[128] It has been shown, however, that a selective analog of the somatostatin receptor subtype 5 (SSTR5) inhibits PRL secretion in a human prolactinoma cell culture.[129] This *in vitro* finding was confirmed *in vivo*: two cases of prolactinoma resistant to CAB treated with Pasireotide LAR, a multiligand somatostatin analog with high affinity for SSTR5, exhibited control of hormonal secretion,[130,131] and tumor reduction was also achieved in one of these cases.[131]

The development of PRL receptor antagonists could also represent an option for medical treatment of resistant macroprolactinomas without mass effects, because they should be able to block the actions of PRL, if not its production.[132] One therapeutic approach would be the association of DAs and PRL receptor-antagonist drugs in cases of macroprolactinomas exhibiting tumor shrinkage but not PRL normalization when on DA monotherapy.

The alkylating agent temozolomide (TMZ) has been experimentally used in many tumors (see also Chapter 15). The drug effect can be reversed by the enzyme methylguanine-DNA methyltransferase (MGMT). TMZ can be given orally and is currently approved for refractory anaplastic astrocytoma and glioblastoma multiforme. Since 2006, it has been used in aggressive/resistant pituitary tumors, mostly in a treatment schedule involving TMZ 150 to 200 mg/m^2/day for 5 days every 28 days. Monitoring of hematological parameters, liver function tests, and careful clinical observation for potential adverse effects during treatment are necessary during chemotherapy. The 2016 European Survey included 25 aggressive prolactinomas and 15 PRL-secreting pituitary carcinomas: nine showed progression, 10 stability, and 19 complete/partial response with TMZ.[133] The European Society of Endocrinology Clinical Practice Guidelines for the management of aggressive pituitary tumors and carcinomas recommend TMZ monotherapy as first-line chemotherapy following documented tumor growth, or in association with radiotherapy (Stupp protocol). Although low MGMT immunohistochemistry expression is associated with a positive response to TMZ, a drug trial may be considered even in cases with high MGMT.[5]

Tyrosine kinase and mTOR inhibitors are potential drugs for resistant/aggressive prolactinomas. Lapatinib, a dual tyrosine kinase inhibitor of both EGF receptor type 1 (EGFR/ErbB1) and 2 (HER2) was able to suppress serum PRL levels and to cause tumor shrinkage in rats with prolactinomas and in two patients harboring aggressive and resistant prolactinomas.[134]

In vitro studies pointed to the effectiveness of antiestrogen treatment in inhibiting PRL secretion and cellular proliferation.[135]

Fig. 4.12 depicts a proposed flowchart for the management of resistant prolactinomas.

Prolactinomas and Pregnancy

The development of efficacious medical and surgical therapies for prolactinomas has made pregnancy possible for women bearing such tumors. Gestational risks owing to the possibility of tumor growth during pregnancy, mainly in women with macroadenomas, raised a

concern, however. The management of pregnancy in patients with prolactinomas who have undergone different therapies is brought into focus here.

To date, the number of pregnancies in women treated with BRC is greater those in women treated with CAB, and therefore BRC is still the only ”authorized” DA for this purpose.[31] In a compilation study of pregnancies in 246 women with microprolactinomas treated with BRC alone, tumor growth symptoms were reported in 1.6% of patients, although an asymptomatic increase in tumor size was shown in 4.5% of the cases. None of the patients needed surgical intervention during pregnancy.[136] We have followed 71 term pregnancies, and the results were similar.[137]

The risk of complications during pregnancy is much greater with macroprolactinomas. A review from the literature pointed to symptoms related to tumor growth in 15.5% of 45 patients with macroprolactinomas treated with BRC alone. The rate of complications was only 4.3% in the 46 patients who underwent surgery or radiotherapy before pregnancy. Additionally, asymptomatic tumor growth was seen in 8.9% of patients without prior surgery or radiotherapy.[136] We followed 51 term pregnancies in patients with macroprolactinomas.[137,138] Of these patients, 21 had had previous surgery, and none presented with symptoms or signs of tumor growth. Of the 30 patients treated with pregestational BRC only, 11 (37%) manifested complaints related to tumor growth: all of them presented with headaches, and seven had visual alterations (Fig. 4.13).

The safety of BRC reintroduction or even maintenance during pregnancy is supported by substantial experience with this DA, as reported in the literature. A large review[139] included 2587 pregnancies and did not show an increase in maternal or fetal morbidity or mortality. Since then, some authors have favored the maintenance of BRC in pregnancy to prevent complications in patients with macroprolactinomas without previous surgery or radiotherapy.[140] The number of pregnancies following treatment with CAB, which has become the DA of choice for prolactinoma treatment, has substantially increased. A recent review did not show any differences in pregnancy outcomes such as abortion, preterm delivery, or fetal malformation in women taking BRC ($n = 6272$) or CAB ($n = 1061$), as compared to the normal population.[141] Recently, we reported that the maternal-fetal outcomes of 233 pregnancies in women being treated with CAB were similar to previous data reported in the literature. Nevertheless, we found a higher miscarriage rate in the subgroup of patients with maintenance of CAB after pregnancy confirmation.[142] The causality of this finding is not established, and more data are needed. The use of CAB for permitting pregnancy is still not approved by the US Food and Drug Administration or and the European Medicines Agency; however, it can be an alternative for BRC-intolerant/resistant cases,[143,144,145] and it should be withdrawn in cases with tumor within sellar boundaries. Of 52 pregnancies in which CAB was maintained, there were three miscarriages, three abortions (one with neural tube malformation), five cases of prematurity, one case of femoral hip dysplasia, and one fetal death because of preeclampsia.[142,146,147,148,149]

In data from 16 series, symptomatic prolactinoma enlargement during pregnancy occurred in 2.5% of cases of microadenomas, 18.1% of cases of macroadenomas without previous surgery or radiotherapy, and 4.7% of cases of macroadenomas with these previous treatments.[141] These data show the higher risk of tumor growth in macroprolactinomas during pregnancy, necessitating stricter follow-up (Fig. 4.14). The first recommendation should be the use of a nonhormonal contraceptive along with a DA until tumor shrinkage to within sellar boundaries has been shown. The duration of previous treatment with DA might be

important.[142,150] After pregnancy has been confirmed, the DA can be withdrawn, and the patient must be closely monitored for symptoms related to tumor growth. If there is suspected tumor expansion, confirmation can be made through noncontrast MRI after the fourth month of gestation, and by visual field testing (see Fig. 4.14). Monitoring serum PRL levels during pregnancy does not seem to be useful, because they are not always related to tumor behavior during gestation. The reintroduction of DA in such cases often leads to clinical amelioration and tumor reduction. In nine of 11 patients who exhibited complications during pregnancy, BRC reintroduction led to complete resolution of the symptoms related to tumor growth.[137] Surgery also can be employed as treatment for symptomatic tumor growth in pregnancy. Several authors have reported good results, although the increased risk of spontaneous abortion in patients who undergo surgery is well known.[137] Regarding DA maintenance throughout gestation, it is our policy to use such an approach only when the patient becomes pregnant after a short treatment period, mainly without confirmation of tumor shrinkage or when the tumor is outside sellar boundaries.

Follow-Up After Delivery. Breastfeeding does not increase the risk of tumor growth in patients who progressed well during pregnancy.[137,144] However, it is contraindicated in patients maintained on DA after delivery, owing to tumor-growth signs.

There have been several reports in the literature regarding reduction or normalization of serum PRL levels after delivery.[137] Remission is reported in 10% to 68% of cases.[137,144,150,151,152] In our multicenter study, normal levels of PRL without DA occurred in 10% of cases. When all patients were considered, 42% presented reduced serum PRL levels, and 46% presented tumor reduction, compared to before pregnancy.[142] The explanation for this "curative" effect of pregnancy remains to be clarified. It may be related partly to modifications in the vasculature of the adenoma attributed to the estrogen stimulation, resulting in necrosis or microinfarctions of the adenomatous tissue. Hemorrhagic zones in prolactinoma patients receiving estrogen therapy have already been described.[153]

Another issue of concern is the outcomes of children whose mothers took DA drugs during pregnancy. One study reported 4-month to 9-year follow-up of 546 children exposed to BRC *in utero*.[139] The authors did not find any developmental impairment in the children. We followed 70 children born to mothers who conceived while taking BRC.[137] At a mean follow-up time of 67 months (range: 12–240 months), only two children presented with disorders of neuropsychomotor development, including one case of idiopathic hydrocephaly and one case of tuberous sclerosis. We did not find any similar reports in the literature. Fifteen of these children already had started puberty, one of them precociously. Regarding the risk of neurodevelopmental impairment attributed to fetal exposure to CAB, no abnormalities were found in two series of five[137] and 99[145] children, respectively. In the other studies, a slight retardation in verbal fluency in two boys and difficulty achieving complete continence in one child were detected among 88 children,[151] seizures in two children and pervasive developmental disorder in two additional children were detected amongst 61 children,[154] and four cases of epilepsy and four cases of delayed neurocognitive development were detected among 145 children.[142]

Treatment Planning and Follow-Up

Based on the previously described data, the current gold-standard therapy for either microprolactinomas or macroprolactinomas is medical treatment with DA drugs. Physicians must motivate patients to embark on such long-term treatment based on the overall better results compared with surgery and, mainly based on more recent data,[76,94] with maintenance of normoprolactinemia after drug withdrawal in a substantial number of patients. Surgical treatment of prolactinomas is indicated for patients with persistent intolerance or hormonal or tumor resistance to more than one DA—particularly if pregnancy is desired—or if the tumor has grown during medical treatment. In cases of resistance, rare conditions such as acidophil stem cell adenoma or PRL-secreting carcinoma should be considered. Malignant prolactinomas respond only temporarily, if they respond at all, when patients are switched to another DA drug or undergo surgery. Surgical therapy is also indicated in selected cases of pituitary apoplexy, in the event that DA–induced CSF leakage occurs in invasive macroprolactinomas, and in the exceedingly rare occurrence of visual loss secondary to optic chiasm herniation during medical therapy. Additionally, surgery in skilled hands may be considered for patients who are not willing to undergo long-term medical therapy, especially patients harboring microprolactinomas and serum PRL levels less than 100 ng/mL.

Radiotherapy, either conventional or stereotactic, is reserved for prolactinomas that not responsive to medical or surgical treatment, particularly invasive ones.

There is evidence that, in general, estrogen replacement is not harmful for women harboring microprolactinomas. This approach may be used when fertility is not an issue for patients with intolerance or resistance to medical therapy and who are not cured by or not willing to undergo pituitary surgery. In addition, women who are successfully medically treated may use hormonal contraceptives if they have not adapted to barrier methods. Menopausal women bearing microprolactinomas can interrupt DA drug use and are allowed to start hormone replacement therapy if is indicated.[125] There is evidence from animal models for a role for PRL in carcinogenesis, mainly carcinoma of the mammary gland, although human data are still highly controversial.[155] It is now apparent that human mammary epithelial cells can synthesize PRL endogenously, permitting autocrine/paracrine actions within the mammary gland that are independent of pituitary PRL and are probably not responsive to DA drugs. At present, the maintenance of high serum PRL levels in premenopausal and postmenopausal women is not a concern with regard to carcinogenesis. Finally, for macroprolactinomas that are not adequately controlled, use of estrogens is generally discouraged, given their potential for growth induction.

There are many therapeutic perspectives for resistant/aggressive prolactinomas: specific somatostatin or somatostatin/dopamine analogs, selective antiestrogen drugs, cytotoxic drugs such as TMZ, and novel PRL-receptor antagonists. Nevertheless, more studies are needed to assess their places in the treatment algorithm.

The follow-up planning for patients with prolactinomas depends on the tumor size and clinical, laboratory, and imaging response to therapy. Many patients are clinically controlled even if serum PRL levels are still above the normal range, and do not need further drug dose increases. For microprolactinomas, and especially for macroprolactinomas, significant tumor shrinkage or "disappearance" on MRI is a good prognostic marker, and in such cases, imaging reassessment can be performed sporadically. Medically or surgically controlled patients must be reassessed periodically, both clinically and hormonally, to identify patients who may discontinue the DA drug with maintenance of normoprolactinemia or patients with recurrence of hyperprolactinemia.

  Growth Hormone Deficiency, 76
  Childhood-Onset Growth Hormone Deficiency in Adults, 77
  Hormone–Hormone Interactions, 77
Pregnancy, 77
Patient Care–Multidisciplinary Approach and Patient Education, 78

HISTORY

Pituitary insufficiency was first convincingly described in the beginning of the nineteenth century by Alfred Frölich, who presented a man with a pituitary tumor, abnormal fat accumulation, and underdeveloped genitalia, a state he called "adiposogenital dystrophy."[1] At about the same time, Joseph Babinski also described a patient with a pituitary tumor and similar clinical features.[2] Undoubtedly, both of these patients suffered from hypopituitarism, at that time called the Babinski–Frölich syndrome.

Since these first descriptions of hypopituitarism, a growing body of scientific discoveries has led us to today's knowledge of pituitary physiology and pathophysiology. In fact, several of the major discoveries that have been awarded the Nobel prize in physiology or medicine are related to the hypothalamopituitary medical field: Houssay in 1947 for discovering the influence of anterior pituitary hormones on glucose metabolism; Kendal, Reichstein, and Hench in 1950 for the discovery of cortisol; Guillemin and Schally in 1977 for the detection and isolation of the hypothalamic hormones thyrotropin-releasing hormone and gonadotropin-releasing hormone (GnRH); Yalow, also in 1977, for the development of radioimmunoassays for peptide hormones; and Lauterbur and Mansfield in 2003 for their pioneering work concerning magnetic resonance imaging.

ETIOLOGY OF HYPOPITUITARISM

A large number of medical conditions can cause hypopituitarism (Table 5.1). The most common cause is a pituitary adenoma, mainly nonfunctioning pituitary adenomas, but also hormone-producing adenomas. In Sweden, the annual incidence of pituitary adenomas between 2001 and 2011 was 3.9 cases per 100,000 inhabitants, and the lifetime risk for developing an adenoma was 0.3%.[3] Approximately 50% of all pituitary adenomas are nonfunctioning, and one third are prolactinomas. Between 40% and 85% of patients with nonfunctioning pituitary adenoma have some degree of pituitary insufficiency at diagnosis, varying from deficient production of one pituitary hormone to panhypopituitarism.[4,5,6] Although pituitary function in some patients can improve following pituitary surgery, development of new hormone deficits is also common.[4,6]

Hypopituitarism is less common in patients with hormone-producing adenomas because the symptoms and signs associated with the hypersecretion draws the attention toward the pituitary at an earlier stage when the adenoma has not reached a sufficient size to affect the function of the pituitary gland. Of note is that pituitary adenomas, both functioning and nonfunctioning, almost never present with diabetes insipidus.

Neoplasms other than pituitary adenomas in the sella region are less common. Many of these, however, like craniopharyngiomas and pituitary metastases, frequently present with multiple pituitary hormone deficiencies, including diabetes insipidus.[7,8] Similarly, when the pituitary gland is affected by a systemic disease such as neurosarcoidosis, Langerhans cell histiocytosis, granulomatosis with polyangitis, and hemochromatosis, panhypopituitarism and diabetes insipidus are also common. Other symptoms related to the underlying disease itself may, however, complicate the clinical picture and delay the detection of hypopituitarism (see also Chapters 6, 7 and 9).

Pituitary cysts are common, especially Rathke's cysts, which are seen in more than 10% of the population.[9] Pituitary cysts are usually small and infrequently causes hypopituitarism. However, large pituitary cysts do occur that may cause pituitary insufficiency. In these cases, the greatest clinical challenge is to differentiate the lesion from a craniopharyngioma or a pituitary adenoma with a large cystic component.

TABLE 5.1 Etiology of Acquired Hypopituitarism in Adults

Pituitary adenomas
Nonfunctioning
Prolactinoma
Acromegaly
Cushing disease
TSHoma

Other neoplasms in the sellar/suprasellar region
Craniopharyngioma
Meningioma
Metastasis
Lymphoma
Germinoma
Teratoma
Pituicytoma
Glioma
Chordoma
Chondrosarcoma
Ependymoma

Pituitary cysts
Rathke's cleft cyst
Epidermoid cyst
Subarachnoid cyst

Hypophysitis
Lymphocytic hypophysitis (autoimmune hypophysitis)
IgG4-related
Checkpoint inhibitor–induced

Pituitary infarction
Sheehan syndrome
Apoplexy

Infiltrative diseases
Sarcoidosis
Langerhans cell histiocytosis
Hemochromatosis
Granulomatosis with polyangitis (Wegener granulomatosis)

Infectious diseases
Abscess
Tuberculoma

Miscellaneous
Pituitary radiotherapy
Pituitary surgery
Radiotherapy for intracerebral tumors and nasopharyngeal cancer
Empty sella
Traumatic brain injury
Opioid-induced

Depending on etiology, patients with hypopituitarism may present with various symptoms other than symptoms related to the hormone deficiencies themselves.

Pituitary insufficiency develops insidiously in most cases. However, there are some important exceptions when this happens acutely. One of these is Sheehan syndrome, an acute infarction of the pituitary gland in women following childbirth, caused by blood loss and hypovolaemia.[10] Another important cause of acute pituitary insufficiency is pituitary apoplexy,(i.e., bleeding into a pituitary adenoma).[11] In both these scenarios, symptoms and signs because of acute secondary adrenal insufficiency dominate the clinical picture. Patients with pituitary apoplexy may also present with local symptoms because of the sudden expansion of the tumour, that is, optic nerve and/or chiasmal compression, ocular pares owing to pressure on the cranial nerves in the cavernous sinus, as well as severe headache, fever, and impaired consciousness resulting from meningeal irritation.

Hypophysitis

Hypophysitis has until recently been considered a rare cause of hypopituitarism. Several different forms of hypophysitis exist; lymphocytic hypophysitis (also called autoimmune hypophysitis) and IgG4-related hypophysitis are the most common.[12] Although hypophysitis can occur at any age in both men and women, lymphocytic hypophysitis typically affects women during late pregnancy or during the first 3 months after delivery. The most common clinical presentation of hypophysitis is headache and hypopituitarism, including ineffective or absent lactation. Symptoms because of cranial nerve compression occurs less often.

With the arrival of new biological drugs, the incidence of hypophysitis has increased substantially.[13] Immune checkpoint molecules can either have an inhibiting or stimulating effect on T-cell function in solid tumors. Both cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) and programmed cell death protein 1 (PD-1) play a pivotal role in the maintenance of immunological tolerance, thereby preventing development of autoimmune disorders. Therefore, when immune checkpoint inhibitors are used for the treatment of cancer, the development of autoimmune disorder is a common side effect. Indeed, autoimmune endocrine disorders are among the most common adverse events related to use of these drugs, including hypothyroidism, hyperthyroidism, hypophysitis, primary adrenal insufficiency, and insulin-dependent diabetes mellitus. Among the commonly used immune checkpoint inhibitors is ipilimumab, a CTLA-4 inhibitor used for treatment of advanced malignant melanoma that causes hypophysitis in up to 10% of patients.[14] Although immune checkpoint inhibitors acting through PD-1 are associated with a much lower incidence of hypophysitis, the combination of CTLA-4 and PD-1 inhibitors seem to be associated with greatest risk of endocrine-related adverse events, including hypophysitis.[15] Of interest is that isolated adrenocorticotropic hormone (ACTH) deficiency is common in patients with immune checkpoint inhibitor–induced hypophysitis, in contrast to patients with pituitary adenoma, who almost always have at least one other pituitary hormone deficiency before they develop secondary adrenal insufficiency.

MORBIDITY AND MORTALITY

Patients with hypopituitarism have increased mortality,[16] as first demonstrated in two seminal studies from Sweden and the United Kingdom.[17,18] Both studies showed a markedly increased mortality (Fig. 5.1), suggesting that management of the underlying disorder, as well as endocrine replacement therapy, could improve. In a metaanalysis including data from six observational studies with over 19,000 hypopituitary patients, the standardized mortality ratio (SMR) was doubled in patients with pituitary insufficiency compared with a reference group, most often the background population (Fig. 5.2).[19] Furthermore, women with hypopituitarism have a higher SMR than men, and young age is associated with higher SMR.[19,20] Other factors that have been found to be associated with increased mortality are inadequate hormone replacement therapy and pituitary radiotherapy, as well as the underlying etiology, such as a craniopharyngioma.[18,21,22] A limitation of most epidemiological studies on mortality (and morbidity) is the inclusion of patients with different causes of pituitary insufficiency. Nevertheless, in a study including only patients with nonfunctioning pituitary adenoma, patients with hypopituitarism still

Excess mortality associated with hypopituitarism in adults: a meta-analysis of observational studies. *J Clin Endocrinol Metab*. 2015;100:1405–1411. Reprinted with permission from Oxford University Press.)

had an increased mortality rate compared with patients with unaffected pituitary function.[20]

Inadequate hormone replacement such as untreated hypogonadotropic hypogonadism, untreated growth hormone (GH) deficiency, as well as nonphysiologic glucocorticoid replacement, may contribute to the increased mortality in patients with hypopituitarism. In fact, patients with untreated hypogonadotropic hypogonadism have a doubled mortality rate compared with their counterparts.[18] It is therefore unfortunate that one-fourth of women of reproductive age with hypogonadotropic hypogonadism are still not receiving estrogen replacement therapy.[23] Similarly, in observational studies, patients with untreated GH deficiency have more than doubled mortality rate compared with patients receiving GH replacement who have an SMR comparable to the background population.[19] Furthermore, patients with ACTH deficiency, especially patients receiving relatively high glucocorticoid doses, have an adverse cardiometabolic profile,[24] as well as increased mortality.[21,22,25,26] Although the excess mortality has mainly been related to the increased risk of cardiovascular and cerebrovascular diseases, deaths from infections are also of importance.[27-29] In fact, patients with secondary adrenal insufficiency have more than 4-fold

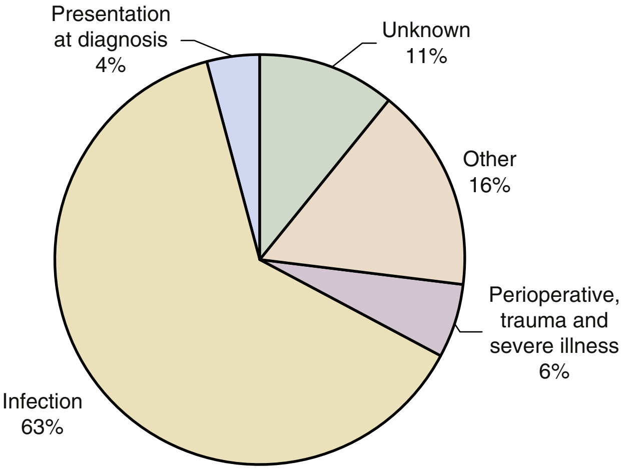

Fig. 5.3 Precipitating Factors of Adrenal Crisis in Patients with Secondary Adrenal Insufficiency. (Modified from Smans LC, Van der Valk ES, Hermus AR, et al. Incidence of adrenal crisis in patients with adrenal insufficiency. *Clin Endocrinol (Oxf)*. 2016;84:17–22.)

increased inpatient admissions because of infections compared with controls,[27] four of 100 patients develop adrenal crisis per year, where infections are the most common cause (Fig. 5.3),[28] and the mortality rate because of infections is six times higher than in the general population.[29]

CLINICAL FEATURES

Clinical features related to hypopituitarism occur insidiously because of gradual loss of anterior pituitary function.

KEY POINTS: Clinical Features in Patients with Hypopituitarism:

Adrenocorticotropic hormone deficiency	**Chronic:** Fatigue, lethargy, weight loss, nausea, and anorexia **Acute:** Nausea, vomiting, hypotension, decreased growth of pubic and axillary hair in women, and hyponatraemia
Thyroid-stimulating hormone deficiency	Fatigue, lethargy, cold intolerance, constipation, dry skin, hair loss, reduced energy, and concentration difficulties
Luteinizing hormone/ follicle-stimulating hormone deficiency	**Women:** Oligomenorrhoea or amenorrhoea **Men:** Erectile dysfunction, decreased muscle mass, decreased hair growth, and anemia **Both:** Sexual dysfunction, infertility, osteoporosis, poor concentration and energy
Growth hormone deficiency	Abdominal obesity, reduced muscle mass, lack of energy and initiative, and impaired quality of life
Prolactin deficiency	Ineffective or absent lactation

However, the clinical presentation can also be dominated by the underlying disorder, such as a pituitary tumor that causes pressure on nearby structures such as the optic nerves, chiasma, and/or the hypothalamus. As symptoms and signs related to a gradual loss of pituitary function are insidious, and often not recognized, the first symptom leading to the diagnosis is therefore frequently loss of visual acuity and/or visual field defects.

When hypopituitarism is suspected, the medical history is of paramount importance, and should include assessment of fatigue and general well-being, metabolic risk factors, changes in body weight and body fat distribution, muscle function, sexual function and fertility, and menstrual history, as well as symptoms related to adrenal insufficiency, in particular the response to previous infections and the recovery time. On physical examination, body composition should be noted, including evaluation of fat distribution and muscle mass, as well as color of the skin, body hair, and testicular volume.

The most common cause of hypopituitarism is a pituitary adenoma. These are mostly slowly growing, and, through pressure on the pituitary, loss of function occurs gradually. Interestingly, this usually occurs in a certain order, which is the same or similar order as in hypopituitarism caused by radiotherapy,[30] where GH and luteinizing hormone (LH)/follicle-stimulating hormone (FSH) deficiencies develop first, followed by thyroid-stimulating hormone (TSH) and ACTH deficiencies, and lastly prolactin deficiency. The reason for this is not clear, but likely reflects the different localization of the hormone-secreting cells in the pituitary and their resistance to pressure and irradiation. Symptoms that occur during the early stage of hypopituitarism are therefore related to GH deficiency and hypogonadotropic hypogonadism.

Isolated GH deficiency is likely a common feature of hypopituitarism during the early stage of its development. GH deficiency in adults is mainly associated with fatigue and abdominal obesity, symptoms that are common in various other and more common conditions, as well as in the general population. Isolated GH deficiency is therefore unlikely to be detected unless other coexisting symptoms and signs related to the underlying disease are also present. Oligo- or amenorrhea caused by hypogonadotropic hypogonadism is also an early and common feature of hypopituitarism in women of fertile age. Again, because other causes than hypopituitarism are much more common, the correct diagnosis is often delayed. Thus, symptoms because of GH deficiency and hypogonadotropic hypogonadism are often nonspecific and less distinct than the clinical features caused by secondary adrenal insufficiency. Diagnostic delay is therefore common.

Although the clinical presentation is most often insidious, more acute presentations may occur. These can be either related to the underlying cause where the order of loss of pituitary function is different from what is seen in a slowly growing pituitary adenoma, or when the cause of hypopituitarism develops suddenly. In both these cases the rapid development of adrenal insufficiency usually makes the clinical course acute. Sheehan syndrome and pituitary apoplexy are examples of disorders that often present with acute panhypopituitarism. Hypophysitis, either autoimmune or because of immune checkpoint inhibitors, and pituitary metastasis, often present with isolated ACTH deficiency. In both of these examples the presentation is more or less acute and may be life-threatening because of an adrenal crisis.

DIAGNOSIS AND ENDOCRINE EVALUATION

Adrenocorticotropic Hormone Deficiency: Secondary Adrenal Insufficiency

Secondary adrenal insufficiency is a potentially fatal condition and should therefore be ruled out in all patients with suspected hypopituitarism and/or a lesion in the hypothalamopituitary region.[31]

KEY POINTS: Biochemical Evaluation of Patients with Suspected Hypopituitarism

Adrenocorticotropic hormone (ACTH) deficiency	Stable patients: • Measure serum cortisol at 8:00 AM. • Serum cortisol >400–450 nmol/L rules out secondary adrenal insufficiency • Serum cortisol <50–100 nmol/L confirms secondary adrenal insufficiency after exogenous glucocorticoid use has been ruled out in patients with symptoms compatible with hypocortisolism • Perform ACTH stimulation test in patients with inconclusive serum cortisol Instable patients: • Collect blood samples for analysis of cortisol and ACTH in acutely ill and/or hemodynamically instable patients, and start empirical treatment with parenteral glucocorticoids without a delay Acute secondary adrenal insufficiency: • ACTH stimulation cannot be used when acute secondary adrenal insufficiency is suspected • Evaluation of suspected acute secondary adrenal insufficiency should be based on clinical features and nonstimulated serum cortisol concentrations
Thyroid-stimulating hormone (TSH) deficiency	• Measure free T4 and TSH • Low or inappropriately normal TSH, together with low free T4, is compatible with central hypothyroidism
Luteinizing hormone (LH)/follicle-stimulating hormone (FSH) deficiency	• Measure LH, FSH and estrogen (women) or testosterone (men) • Low or inappropriately normal LH and FSH, in combination with low concentrations of estrogen in women and low testosterone in men, is compatible with hypogonadotropic hypogonadism • Measure serum prolactin to rule out hyperprolactinemia as a cause for hypogonadotropic hypogonadism
Growth hormone (GH) deficiency	GH stimulation tests (GH peak is test-specific): • Insulin tolerance test • Arginine–GH–releasing hormone test • Glucagon stimulation test • MacimorelinIn patients with more than three anterior pituitary hormone deficiencies and low serum insulin-like growth factor 1, a GH stimulation test may not be needed

Also, secondary adrenal insufficiency has a pronounced negative impact on general well-being and quality of life that improves substantially with glucocorticoid replacement therapy.

In hemodynamically stable patients, secondary adrenal insufficiency can be ruled out if morning serum cortisol is greater than 400 to 450 nmol/L.[32,33] On the contrary, in patients with serum cortisol less than 50 to 100 nmol/L, secondary adrenal insufficiency can be considered to be confirmed in patients with symptoms compatible with adrenal insufficiency, and after use of exogenous glucocorticoids has been ruled out. In patients with a serum cortisol between 100 and 400 nmol/L, ACTH stimulation (also called the *synacthen* or *cosyntropin* test) is needed to rule out or confirm secondary adrenal insufficiency. During the test, serum cortisol is measured before, as well as 30 and/or 60 minutes after, a synthetic ACTH is injected intravenously or intramuscularly. Serum cortisol that exceeds 400 to 450 nmol/L can be considered an adequate response in most assays. Patients without an increase in serum cortisol, on the other hand, have adrenal insufficiency. Patients in whom serum cortisol increases following ACTH stimulation compared to the pretest value, but does not exceed 350 to 450 nmol/L, may be considered to have partial adrenal insufficiency. How and whether this should be replaced with daily doses of glucocorticoids, or only during intercurrent illness, should be based on the overall clinical picture of the individual patient. In the clinical setting where it is difficult to differentiate between primary and secondary adrenal insufficiency, plasma ACTH should also be measured. ACTH in patients with primary adrenal insufficiency is usually greatly elevated, whereas in patients with secondary adrenal insufficiency it is either low or inappropriately normal.

Traditionally, 250 µg of ACTH have been used for the stimulation test. However, because 250 µg is a supraphysiological dose, it has been suggested that a lower dose with 1 µg may be more adequate for the evaluation of secondary adrenal insufficiency. However, studies that have compared the two doses have not been able to support the superiority of either dose.[34] Another test used to diagnose secondary adrenal insufficiency is the insulin tolerance test, often considered to be the gold standard for evaluation of the hypothalamus-pituitary-adrenal (HPA) axis. During the test, insulin is administrated intravenously to provoke hypoglycemia, which has a powerful stimulating effect on CRH, arginine vasopressin, ACTH, and, subsequently, cortisol production. The main advantage with the test is that the whole HPA is tested, and that GH secretion, also stimulated by hypoglycemia, can be tested simultaneously. However, the test is cumbersome, is not without risks, and is contraindicated in patients with cardiovascular disease, patients with epilepsy, and in the elderly. Thus, the insulin tolerance test should only be done in units with sufficient experience in performing the test.

In the acutely ill and/or hemodynamically unstable patient, the greatest challenge is to think of secondary adrenal insufficiency as a differential diagnosis. If secondary adrenal insufficiency is suspected, blood samples should be collected immediately for analysis of plasma ACTH and serum cortisol. Empirical treatment with parenteral glucocorticoids should be initiated thereafter without delay and before the results from the biochemical analyses have arrived. No clear cutoff cortisol concentrations are available to confirm or rule out secondary adrenal insufficiency in a critically ill patient. Serum cortisol concentrations increase during stress, and the cutoff used to rule out adrenal insufficiency in otherwise stable patients (400–450 nmol/L) is, therefore, probably too low in the acute setting.

Secondary adrenal insufficiency usually develops gradually. However, there are some exceptions when secondary adrenal insufficiency develops acutely, (e.g., following pituitary surgery and in association with pituitary apoplexy or Sheehan syndrome). ACTH stimulation cannot be used under these circumstances. During chronic secondary adrenal insufficiency, a gradual downregulation of ACTH receptors occurs in the adrenal cortex. Thus, when acute secondary adrenal insufficiency develops, this downregulation has not occurred yet, and serum cortisol increases to normal concentrations following administration of exogenous ACTH. Evaluation of suspected acute secondary adrenal insufficiency should therefore be based on the clinical features and nonstimulated cortisol concentrations in serum.

ACTH also stimulates the production of androgens from the adrenal cortex. Thus, women with ACTH deficiency develop not only secondary adrenal insufficiency, but also androgen deficiency. Low concentrations of dehydroepiandrosterone (DHEA) sulfate in serum support the diagnosis.

Thyroid-Stimulating Hormone Deficiency: Central Hypothyroidism

Central hypothyroidism is, in the vast majority of cases, part of a more extensive hypopituitarism. Isolated central hypothyroidism may, however, occur in relation to specific underlying etiologies, such as hypophysitis induced by checkpoint inhibitors, as well as congenital causes that are most often diagnosed during neonatal screening or in early childhood. Genetic testing should be done in familial cases of central hypothyroidism and in cases where the etiology remains unexplained after initial evaluation, including imaging studies of the pituitary gland.[35] Symptoms and signs that are specifically related to central hypothyroidism may not be as striking as in patients with overt primary hypothyroidism, as these are often masked by symptoms and signs related to other pituitary hormone deficiencies.

Central hypothyroidism is diagnosed biochemically by measuring free T4 and TSH.[35] Subnormal concentrations of free T4, together with low or inappropriately normal serum TSH, should raise the suspicion of central hypothyroidism. In some cases, mainly where the cause is because of hypothalamic dysfunction, TSH concentrations may even be slightly elevated. In these cases, the circulating TSH has normal immunoreactivity but low bioactivity.

In patients with a well-defined hypothalamopituitary disorder who have low free T4 and inappropriately low TSH concentrations, the diagnosis of central hypothyroidism is obvious. In less distinct cases, the free T4 and TSH measurements should be repeated, and other causes such as nonthyroidal illness and drugs that reduce TSH secretion, such as glucocorticoids, dopamine, antiepileptics, antipsychotics, and metformin, should be ruled out. In milder forms of central hypothyroidism, free T4 concentration can be in the low-normal reference range, and a trial of L-thyroxine replacement may be of value. Also, patients with unreplaced GH deficiency may have central hypothyroidism despite a free T4 concentration in the low-normal range, because of reduced conversion of T4 to T3.[36]

Luteinizing Hormone/Follicle-Stimulating Hormone Deficiency: Hypogonadotropic Hypogonadism

The clinical presentation of hypogonadotropic hypogonadism depends on age and gender. In women of premenopausal age, menstrual disorder with either oligo- or amenorrhea and postmenopausal symptoms are typical. Common complaints in men are reduced muscle strength, increased fat accumulation, loss of masculine bodily hair, reduced frequency of shaving, fatigue, and impotence. Reduced libido or infertility can also be dominating symptoms in both genders.

Hypogonadotropic hypogonadism is characterized biochemically by low or inappropriately normal LH and FSH, in combination with low concentrations of estrogen in women and low testosterone in men.[37] Because hyperprolactinaemia, even of modest grade, is a common cause of hypogonadotropic hypogonadism, serum prolactin should always be measured. Biochemical confirmation of hypogonadotropic hypogonadism is essential in men and women of premenopausal age before replacement therapy is started. However, the clinical value of diagnosing hypogonadotropic hypogonadism in postmenopausal women, characterized by the same biochemical picture as in women of reproductive age, is limited.

Growth Hormone Deficiency

In patients with an expanding structural lesion within the hypothalamopituitary region, and in patients who have received pituitary radiation, GH is the first pituitary hormone to suffer. Therefore, GH deficiency is present in most patients with hypopituitarism and should be suspected in all patients with a hypothalamopituitary disorder. The diagnosis of GH deficiency is based on biochemical testing because most symptoms and signs related to GH deficiency, such as fatigue, concentration difficulties, lack of initiative, abdominal fat accumulation, and dyslipidemia, are nonspecific. Because endogenous GH secretion is highly pulsatile, with most of the GH secretion occurring during sleep and low GH concentrations during daytime, a GH stimulation test is needed in most cases to confirm the diagnosis.

GH is a powerful metabolic hormone that, through its action on the GH receptor and generation of endocrine and paracrine insulin-like growth factor 1 (IGF-1), induces effects in most organs in the human body.[38] Clinically, GH treatment is best known for its effects on the growth plate. In children with short stature because of GH deficiency, GH replacement increases growth velocity, and normal final height is frequently obtained (see also Chapters 17 and 18). The biological effects of GH are, however, much more diverse. GH and its interplay with insulin in fasting and fed states regulates metabolism and energy storage.[39] GH secretion is suppressed after ingestion of food and increases in the fasting state. GH increases mobilization of energy by inducing lipolysis and insulin resistance during fasting, and simultaneously promotes protein synthesis. GH also affects lipoprotein and lipid metabolism by upregulation of the low density lipoprotein receptor in the liver and increasing the hepatic output of very low density lipoproteins.[40] GH also increases bone resorption and bone formation, and thereby bone remodeling, through its effects on both osteoclasts and osteoblasts.[41] Furthermore, GH and IGF-1 have multiple effects on the cardiovascular system, including an inotropic effect on the heart muscle, and reducing peripheral vascular resistance, mediated by increased endothelial production of nitric oxide.[42] GH and IGF-1 are also found in the cerebrospinal fluid,[43] and GH and IGF-1 receptors are expressed in cells in the central nervous system, illustrating the importance of GH and IGF-1 for normal brain function.

Symptoms and Signs. Based on the physiological effects of GH in various clinical and experimental systems, some symptoms and signs related to adult GH deficiency may be expected. The best-described consequences of GH deficiency in adults are related to changes in body composition.[44] GH-deficient patients have increased body fat mass with abdominal preponderance, reduced muscle mass and strength, and reduced extracellular water. Reduced bone mineral density has also been associated in adults with GH deficiency, although data related to whether fracture risk is increased are less clear, although this has been suggested in some studies.[41] Dyslipidemia is also common, where triglycerides, total- and low density lipoprotein–cholesterol are increased, and high density lipoprotein–cholesterol is reduced, a lipid pattern associated with increased risk of cardiovascular disease.[44] Reduced cardiac output, endothelial dysfunction, and increased sympathetic nerve activity have also been shown in adults with GH deficiency.[42,45] Furthermore, quality of life and general well-being are frequently compromised.[46] Most of the features mentioned above improve or even normalize in response to GH replacement. It should, however, be recognized that most studies on clinical features in adults with GH deficiency have included subjects with severe hypopituitarism. Therefore, some of the clinical features considered to be associated with adult GH deficiency my actually be caused by inadequate replacement with other pituitary hormones, or effects of the underlying disease itself.[47]

Diagnosis. Diagnosis of GH deficiency in adults should be performed in the context of a well-defined hypothalamopituitary disorder (Table 5.1) where the probability of GH deficiency is high.[48-50] The main reason is that the specificity of the tests in an unselected population is often low, partially explained by a strong negative impact of obesity, in particular abdominal obesity, on GH secretion, and overdiagnosis of GH deficiency can therefore be avoided. Diagnosis of GH deficiency should also only be performed in patients where other pituitary function has been thoroughly evaluated and hormone deficiencies adequately replaced.

Various stimulation tests have been used and validated for the diagnosis of GH deficiency in adult, including the insulin tolerance test, arginine (Arg)-GH releasing hormone (GHRH), glucagon, Arg alone, GH-releasing peptide (GHRP) 2 and 6, as well as GHRP in combination with GHRH. The insulin tolerance test, previously used primarily to diagnose adrenal insufficiency, was evaluated early for the diagnosis of GH deficiency in adults.[51] In patients with well-established hypopituitarism, the insulin tolerance test convincingly identifies patients with GH deficiency by using a cutoff of 3 μg/L, and 5 μg/L in younger subjects. Also, results from the test are not markedly affected by obesity. However, it is labor-intensive, the hypoglycemia that is induced is inconvenient for the patient, and, because of safety, should not be used in the elderly and in patients with ischemic heart disease or epilepsy. In experienced centers its use is safe and the repeatability is high.

The combined Arg-GHRH test is also well-validated for the diagnosis of GH deficiency in adults. The GH peak obtained with the test has a high correlation with the results from the insulin tolerance test, and the repeatability is high. The cutoff used to diagnose GH deficiency with Arg-GHRH is body mass index (BMI)-dependent, with lower peaks in obese than in lean subjects (BMI <25, 11.5 μg/L; 25< BMI ≤30, 8 μg/L; BMI ≥30, 4.2 μg/L).[52] The test is well-tolerated by patients, but is limited by frequent false-negative results in patients who have received radiation therapy toward the hypothalamopituitary area, for up to 5 years after treatment, because GHRH directly stimulates the pituitary gland.[53] Other commonly used agents are glucagon and Arg alone. Both are well tolerated but limited by weight-dependent peak GH response. Therefore, by using the traditional cutoff of 3 μg/L, overdiagnosis of GH deficiency in obese subjects is common, and a more stringent criterion of 1 μg/L has been suggested, at least for the glucagon stimulation test.[48]

The GH secretagogue macimorelin was recently developed for the diagnosis of GH deficiency in adults.[54] The test allows oral administration of macimorelin after 8 hours of fasting, with collection of blood samples for GH in serum before administration and at 30, 45, 60, and 90 minutes after. The most frequent side effect is mild and transient dysgeusia. The correlation between the peak GH response in response to insulin tolerance test and macimorelin is very high, as is the repeatability. The suggested cutoff for the diagnosis of GH deficiency is 5.1 μg/L. The main limitations of macimorelin is that it is contraindicated in patients taking drugs that prolong the QT interval on electrocardiogram and cannot be used together with drugs that induce CYP3A4 (such as carbamazepine, phenytoin, rifampin, St. John's wort), because increased CYP3A4 activity may reduce the serum concentration of macimorelin and, therefore, give false-positive results.

Hypopituitarism Following Pituitary Surgery

Although pituitary function can improve following pituitary surgery in some patients, the development of new hormone deficiencies is more common.[55] Most important is to rule out secondary adrenal deficiency by measuring serum cortisol after stopping all glucocorticoid treatment for 24 hours. A very low cortisol (<100 nmol/L) is compatible with adrenal insufficiency, while values above 400 to 450 nmol/L rule it out. The remaining patients, with values between 100 and 400 nmol/L, should be followed closely until the adrenocortical function can be tested adequately with a synacthen test or insulin tolerance test approximately 6 weeks postoperatively. With this approach, new postoperative adrenal insufficiency, as well as restoration of normal cortisol production in some cases, can be detected.

Thyroid function should also be tested during the early postoperative period. However, because thyroxine has a relatively long half-life, a significant decrease in free T4 concentrations is typically first seen 1 week after surgery in patients who have developed central hypothyroidism. Because hypopituitarism following pituitary surgery develops acutely, dose titration of L-thyroxine with a low starting dose is not necessary.

Evaluation of gonadal function and GH secretion should not be done in the early postoperative period, because the anesthesia and the operation itself may have a significant effect on their secretions. Instead, evaluation of the gonadal axis should be reevaluated approximately 3 months postoperatively, and GH production 6 to 12 months following surgery, when other hormone deficiencies have been adequately evaluated and treated.[55]

HORMONE REPLACEMENT THERAPY

Adrenocorticotropic Hormone Deficiency: Secondary Adrenal Insufficiency

Glucocorticoid replacement therapy is essential for all patients with secondary adrenal insufficiency.[32] Hydrocortisone is the most commonly used glucocorticoid. Hydrocortisone has the same chemical structure as endogenously produced cortisol and has a relatively short half-life (1.5 hours), which makes it suitable for replacement where the dose and timing of intake can be used to mimic the physiological diurnal variation of cortisol production (Fig. 5.4). In some countries, cortisone

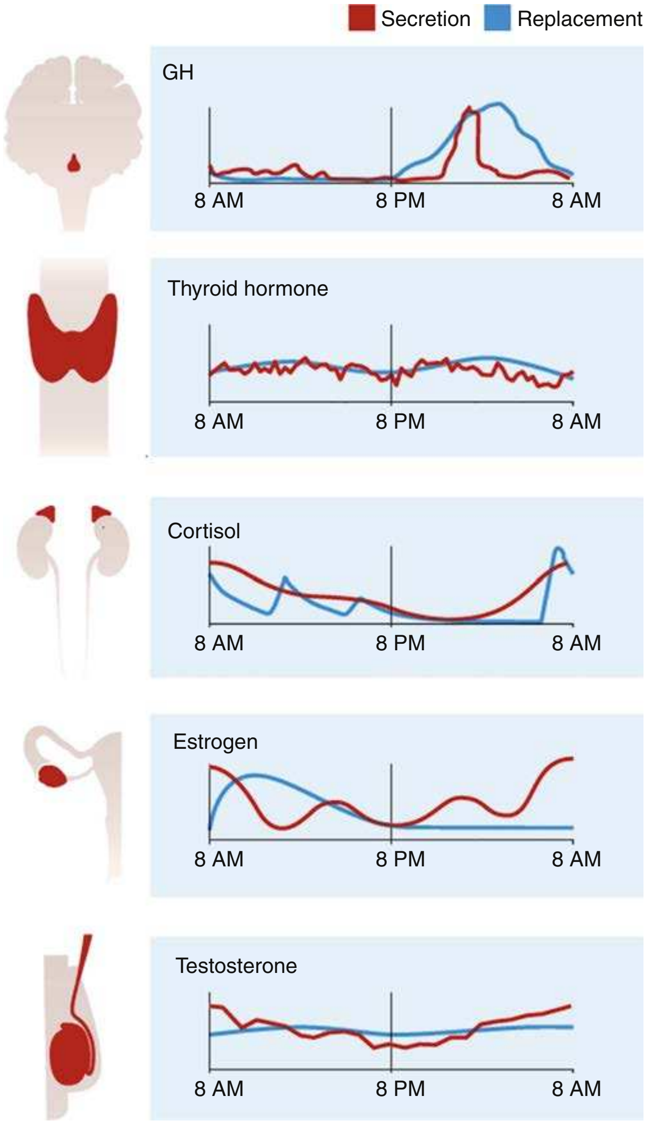

Fig. 5.4 Schematic Illustration of the Different Hormone Profiles in Serum During Normal Physiological Secretion *(Red Lines)* and Hormone Replacement *(Blue Lines)*. *GH,* Growth hormone.

acetate, also with a relatively short half-life, is the preferred glucocorticoid for patients with adrenal insufficiency. Two observational studies have demonstrated a better cardiometabolic profile in patients receiving cortisone acetate compared with hydrocortisone.[24,56] This may be explained by the fact that the glucocorticoid potency of hydrocortisone in relation to cortisone acetate is probably underestimated, that is, the assumption that 20 mg hydrocortisone equals 25 mg cortisone acetate is not correct. Replacement therapy with glucocorticoids such as prednisolone and dexamethasone, with a considerably longer half-life and higher potency, is rarely advocated.[33]

Hydrocortisone is usually administrated in two or three divided doses per day.

KEY POINTS: Treatment of Hypopituitarism

Adrenocorticotropic hormone deficiency	• Hydrocortisone (or cortisone acetate) in two or three divided doses, 15–20 mg per day, with the highest dose taken upon awakening • Administer increased glucocorticoid dose during stress (see following Key Points box) • Consider androgen replacement in women with secondary adrenal insufficiency
Thyroid-stimulating hormone (TSH) deficiency	• L-thyroxine is the preferred treatment • Low starting dose with dose titration aiming at free T4 concentration in the upper-normal reference range • TSH concentrations cannot be used to guide dose titration
Luteinizing hormone/follicle-stimulating hormone deficiency	• Women of premenopausal age: estrogen, together with progesterone if the uterus is intact • Women of postmenopausal age: no treatment needed • Men: testosterone
Growth hormone (GH) deficiency	• The initial daily GH dose should be no higher than 0.1–0.3 mg to avoid side effects • Higher starting dose can be used in the young, in particular in young women receiving oral estrogen replacement • The dose titration should be done cautiously to avoid side effects • Serum insulin-like growth factor 1 concentration should be normalized and preferably targeted at the upper-normal reference range

The first dose is taken upon waking, and the subsequent dose 4 to 6 hours later. A higher dose is administered in the morning than in the noon/afternoon to mimic the circadian cortisol production and exposure. Based on studies on cortisol production in healthy adults, 10 to 15 mg of hydrocortisone and 15 to 20 mg of cortisone acetate can be considered to be near-physiologic doses.[57,58] Thus, a typical dose regime for patients taking 15 mg hydrocortisone per day would be 10 mg upon awakening and 5 mg 6 hours later. In patients who experience symptoms because of hypocortisolemia before the second dose, a three-dose regime may be more appropriate, (e.g., 10+5+2.5 mg with ~4 hours in between). Although 10 to 20 mg of hydrocortisone per day is sufficient for most patients, some will need higher doses to achieve a satisfactory effect on quality of life. Doses of 30 mg or higher should, however, be avoided. In fact, high glucocorticoid replacement doses in patients with secondary adrenal insufficiency are associated with a higher BMI and low density lipoprotein, greater waist circumference, worse quality of life, and increased mortality (Fig. 5.5).[21,22,24,25,59] Recently, a new dual-release hydrocortisone formulation has been approved in Europe.[60] The tablet, administered once daily, consists of two components: a coating that is released immediately after ingestion, and a modified-release core. In comparison to conventional hydrocortisone replacement, this dual-release formulation provides a more physiological glucocorticoid exposure (Fig. 5.6) and seems to have beneficial effects on quality of life as well as cardiometabolic outcome.[61]

Patients with partial secondary adrenal insufficiency, (i.e., where serum cortisol increases following ACTH stimulation but does not exceed 350 to 450 nmol/L, depending on the assay), should receive individualized glucocorticoid replacement. Some of these patients need the same regime as patients with complete secondary adrenal insufficiency, others need chronic treatment but with lower doses (5–10 mg per day), and some may only need glucocorticoids during episodes of intercurrent illness.

Women with ACTH deficiency not only lack adequate cortisol production, but also have inadequate androgen production. Androgen replacement in women with secondary adrenal insufficiency may have beneficial effects on mood, sexual health, and general well-being.[62,63] For this purpose, orally administered DHEA (12.5–25 mg per day) is often used. However, the treatment response varies greatly. Some patients experience a clear beneficial effect, while others do not. Also, side effects such as acne, oily hair, and greasy skin are common, even with low doses. Current clinical guidelines recommend against routine replacement with androgens to women with adrenal insufficiency.[64] Thus, until more data on safety and effectiveness are available, decisions about androgen replacement should be made on an individual level.

The renin-angiotensin-aldosterone system in patients with secondary adrenal insufficiency is intact. Thus, unlike patients with primary adrenal insufficiency, patients with secondary adrenal insufficiency do not need aldosterone replacement.

Patients with secondary adrenal insufficiency, just like patients with Addison disease, need higher doses of glucocorticoids during times of increased physiological and psychological stress (Fig. 5.7).

KEY POINTS: Glucocorticoid Treatment During Stress

Fever	Double or triple the glucocorticoid dose until recovery
Gastroenteritis	50–100 mg hydrocortisone intramuscularly (IM) or intravenously (IV), followed by 100–200 mg per 24 h as continuous infusion or boluses of 50 mg every 6 h, together with liberal amounts of isotonic fluids
Minor procedures (e.g., tooth extraction)	Extra glucocorticoid dose before the procedure, e.g., 20 mg hydrocortisone
Invasive procedures	50–100 mg hydrocortisone IM or IV before start of the procedure
Major surgery	50–100 mg hydrocortisone IV before anesthesia, followed by 100–200 mg per 24 hours, together with IV fluids
Acute adrenal crisis	100 mg hydrocortisone IV, followed by 100–200 mg per 24 hours as continuous infusion or boluses of 50 mg every 6 hours, together with liberal amounts of isotonic fluids

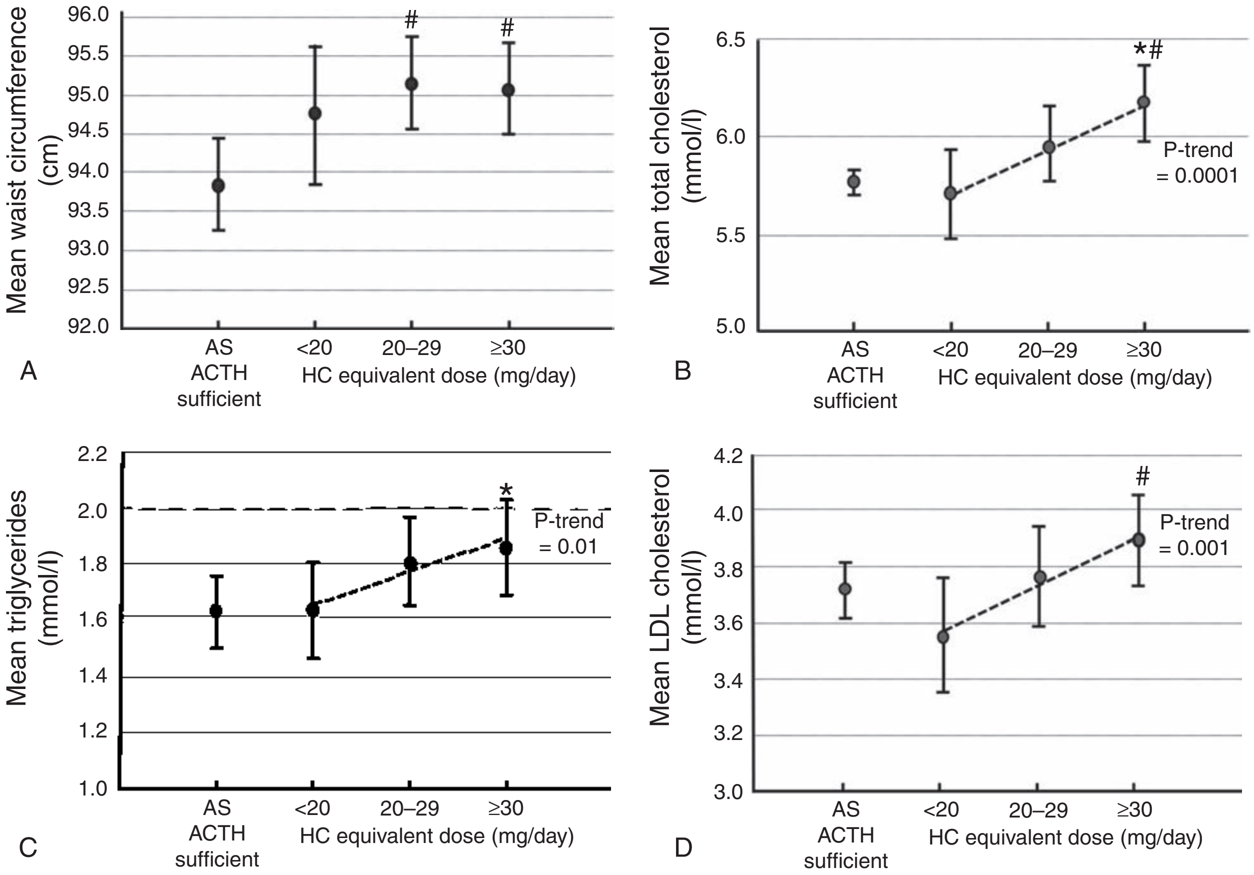

Fig. 5.5 The mean waist circumference (**A**), total cholesterol (**B**), triglycerides (**C**), and LDL-cholesterol (**D**) in adrenocorticotropic hormone (*ACTH*)-sufficient (*AS*) patients, compared with patients with secondary adrenal insufficiency receiving <20 mg, 20–29 mg, or ≥30 mg hydrocortisone per day. *HC,* hydrocortisone. This is of paramount importance, because death from adrenal crisis is an important, and potentially avoidable, contributor to the increased mortality observed in patients with pituitary insufficiency.[29] A cornerstone in the management of patients with adrenal insufficiency during intercurrent illness is to prevent acute adrenal crisis by increasing the regular replacement dose in a timely manner. Although different regimes exist, doubling the glucocorticoid dose is usually sufficient, (i.e., patients receiving 10 mg hydrocortisone in the morning and 5 mg in the afternoon should take 20+10 mg instead). In patients with recurrent vomiting and/or diarrhea, where the gastrointestinal uptake of hydrocortisone is uncertain, glucocorticoids have to be administrated parenterally. Patients who present with acute adrenal crisis also need parenteral treatment with glucocorticoids. In addition, because most patents with adrenal crisis are dehydrated, abundant amounts of intravenous fluids are needed.

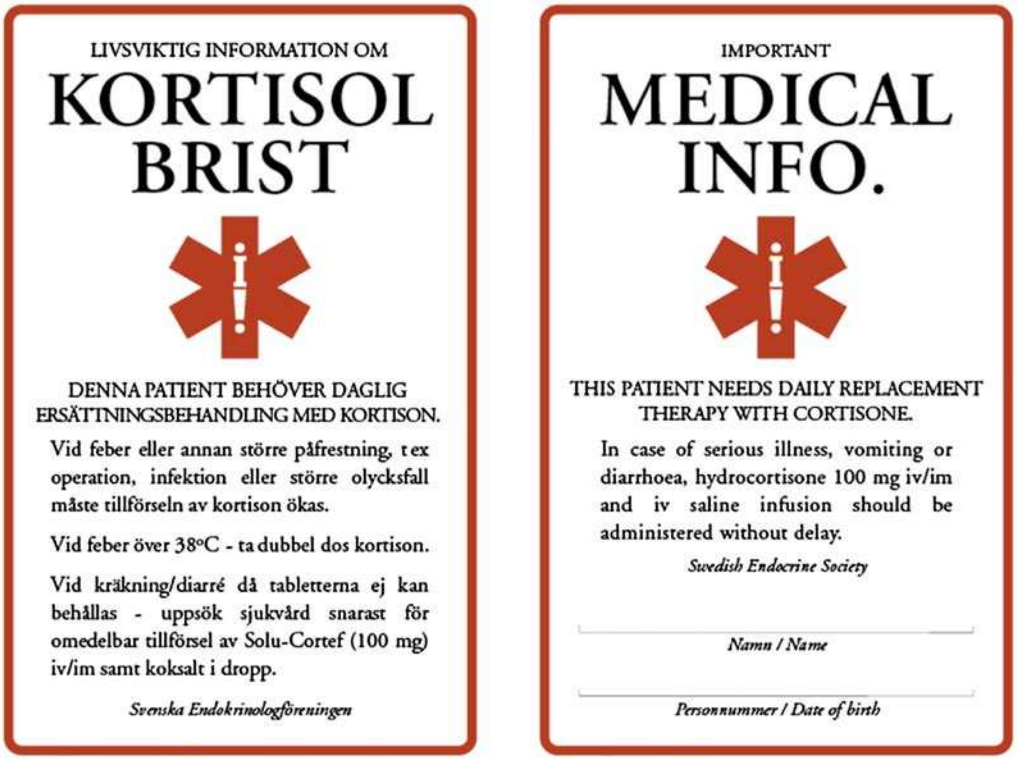
Thyroid-Stimulating Hormone Deficiency Central Hypothyroidism

L-thyroxine is the standard replacement therapy for patients with central hypothyroidism. Because of its long half-life (7 days), once-daily administration is sufficient, where a peak serum concentration of free T4 is reached 2 to 3 hours after ingestion.[35] L-thyroxine replacement does not mimic the normal small diurnal variations in free T4



LIVSVIKTIG INFORMATION OM

KORTISOL BRIST

DENNA PATIENT BEHÖVER DAGLIG ERSÄTTNINGSBEHANDLING MED KORTISON.

Vid feber eller annan större påfrestning, t ex operation, infektion eller större olycksfall måste tillförseln av kortison ökas.

Vid feber över 38°C - ta dubbel dos kortison.

Vid kräkning/diarré då tabletterna ej kan behållas - uppsök sjukvård snarast för omedelbar tillförsel av Solu-Cortef (100 mg) iv/im samt koksalt i dropp.

Svenska Endokrinologföreningen

IMPORTANT

MEDICAL INFO.

THIS PATIENT NEEDS DAILY REPLACEMENT THERAPY WITH CORTISONE.

In case of serious illness, vomiting or diarrhoea, hydrocortisone 100 mg iv/im and iv saline infusion should be administered without delay.

concentrations entirely, with peaks between 8:00 AM and 12:00 AM and troughs between 11:00 PM and 3:00 AM. Whether this difference is of clinical significance is not known.

Initiating L-thyroxine replacement should not be done unless adrenal insufficiency has first been ruled out. The reason is that L-thyroxine increases the metabolic clearance rate of cortisol, and thereby increases the risk of adrenal crisis in subjects with untreated adrenal insufficiency. Careful evaluation of HPA functions should therefore be done in all patients with central hypothyroidism, because the probability of coexisting adrenal insufficiency is high.

A common starting dose of L-thyroxine is 25 µg per day. However, the initial dose for the elderly and patients with cardiovascular disease should be lower. The dose of L-thyroxine should then be titrated, aiming at a serum free T4 concentration in the mid or upper part of the normal reference range. A common strategy is to increase the dose by 25 µg every 4 to 6 weeks until the goal has been reached. Again, dose titration in the elderly and subjects with cardiovascular disease should be done at a slower pace and in smaller dose steps. In prospective dose titration studies, an optimal L-thyroxine dose in subjects younger than 60 years was 1.4 to 1.7 µg/kg per day, and 1.1 to 1.4 µg/kg per day in patients older than 60 years.[65] A careful dose titration, where free T4 reaches the mid- or upper-normal reference range, is supported by studies showing beneficial effects on cardiovascular risk factors (Fig. 5.8).[66,67] Thus, to obtain optimal L-thyroxine dose, free T4 should be measured before the morning dose is taken, aiming at a concentration in the mid or upper part of the normal range, and symptoms and signs related to over- or under-treatment should be avoided. TSH, used to adjust L-thyroxine dose in patients with primary hypothyroidism, cannot, for obvious reasons, be used for patients with central hypothyroidism.

Luteinizing Hormone/Follicle-Stimulating Hormone Deficiency: Hypogonadotropic Hypogonadism

Women of reproductive age with hypogonadotropic hypogonadism should receive treatment with estrogen, and progesterone if the uterus is intact.[32,37] In many cases, a relatively high doses of estrogen are needed to relieve the postmenopausal symptoms, (e.g., 2 mg orally or 75 to 100 µg with transdermal patches). The goals with treatment are to improve quality of life, preserve bone mineral density, and prevent premature death. Women of postmenopausal age with hypogonadotropic hypogonadism do usually not require any specific replacement therapy.

Men with hypogonadotropic hypogonadism should receive replacement therapy with testosterone, either administrated intramuscularly at regular intervals, or with a transdermal gel formulation once daily, or an oral formulation that was recently approved by the US Food and Drug Administration.[68] The goals with treatment are to improve quality of life and sexual function, increase bone mineral density, muscle mass, and muscle strength, and regain normal fat distribution. Before the treatment is initiated, undiagnosed prostate cancer should be ruled out by clinical examination of the prostate gland and by measuring prostate-specific antigen. During testosterone replacement therapy, testosterone in serum should be measured at regular intervals to ensure adequate concentrations. In addition, because secondary polycythemia is the most common side effect of testosterone treatment, hematocrit should also be measured at least annually. In patients who develop polycythemia (hematocrit >48%–50%), the testosterone dose should be reduced, and other reasons such as obstructive sleep apnea should be considered.

Premenopausal women with hypogonadotropic hypogonadism who wish to become pregnant should be offered reproductive treatment,

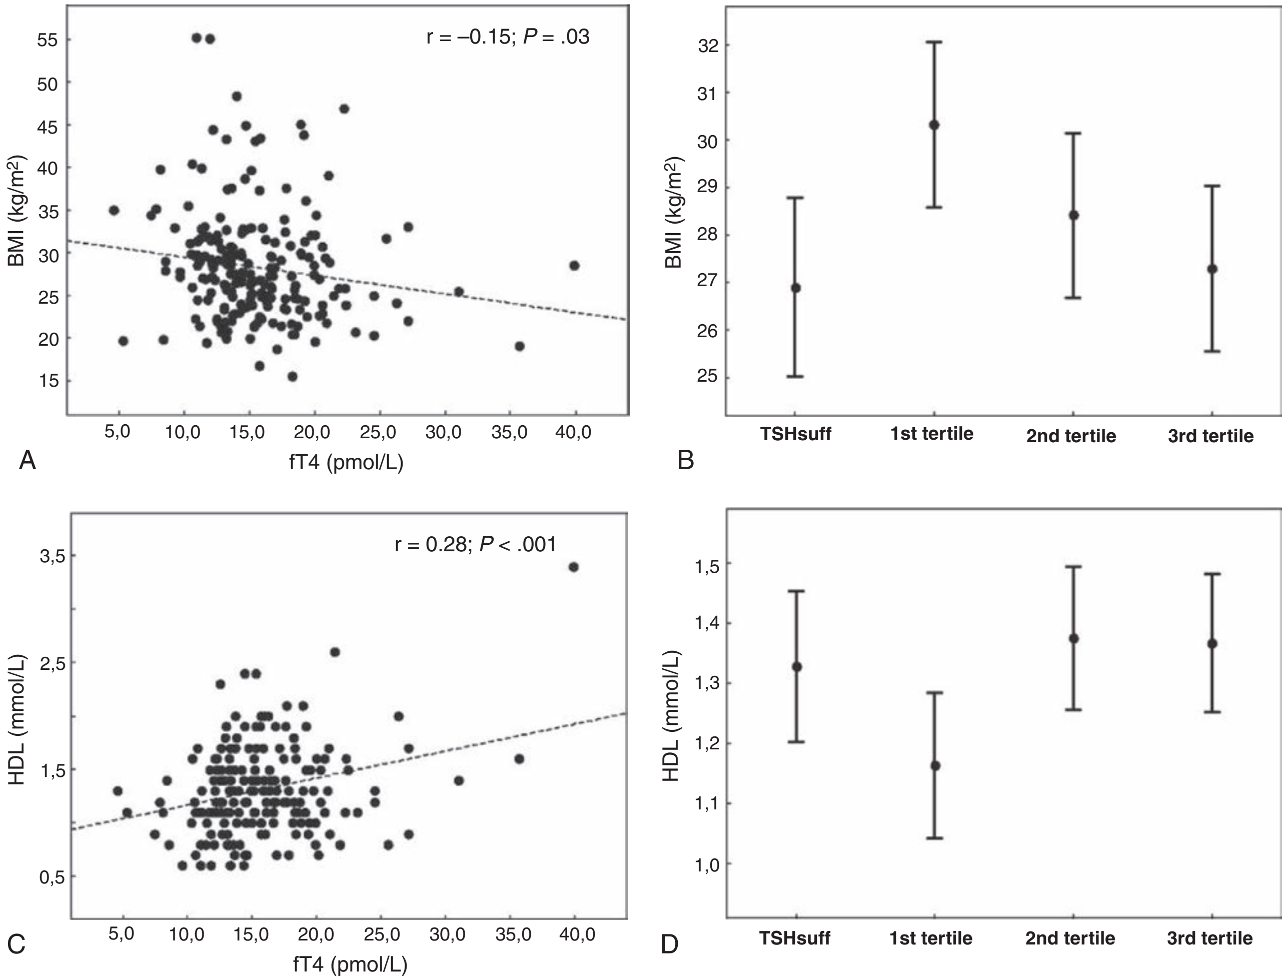

Fig. 5.8 The association between free T4 (fT4) concentrations and body mass index (*BMI*) (**A**) and high density lipoprotein (*HDL*)-cholesterol (**C**), as well as the relationship between L-thyroxine treatment and BMI (**B**) and HDL-cholesterol (**D**) in 208 patients with hypopituitarism. *TSHsuff,* Thyroid-stimulating hormone–sufficient. (From Klose M, Marina D, Hartoft-Nielsen ML, et al. Central hypothyroidism and its replacement have a significant influence on cardiovascular risk factors in adult hypopituitary patients. *J Clin Endocrinol Metab.* 2013;98:3802–3810. Reprinted with permission from Oxford University Press.)

with gonadotropins administered subcutaneously or with GnRH analogs administered via pump. Although fertility is greatly reduced in women with hypopituitarism, ovulation can be induced in up 75%.[69] Similar treatment should be offered to men with hypogonadotropic hypogonadism, where sufficient spermatogenesis can be induced in the majority of patients with hypopituitarism acquired during adulthood and successful pregnancy in approximately one-third.[70]

Growth Hormone Deficiency

Although GH has been approved for adults with GH deficiency for more than 20 years, and international guidelines recommend treatment to eligible patients, far from all patients with hypopituitarism and GH deficiency receive GH replacement therapy.[48-50] In many countries, the main reason is economical restrictions and lack of reimbursement. The reason why GH is not prescribed to GH-deficient patients in many developed countries is less clear. Nevertheless, this means that there is a selection of adult patients who receive GH replacement, which should be considered when data on efficacy and outcome are interpreted.

Most studies that have investigated the effects of GH replacement on body composition, lipid metabolism, quality of life, and general well-being indicate that patients with the most severe phenotype improve the most. There are no strong data supporting the idea that the beneficial effects of GH replacement are affected by age, gender, or underlying disease. Thus, clinically applicable scoring systems, or cutoffs, for selection of patients who theoretically benefit most from GH replacement have not yet been developed. Therefore, current guidelines state that all eligible patients with a well-defined hypothalamopituitary disease and high likelihood of GH deficiency should be tested and offered treatment if they fail the test.[48-50]

Before initiating GH treatment, the underlying condition, other pituitary hormone deficiencies, and their replacement, the risk of diabetes mellitus, and cardiometabolic status, should be carefully evaluated. GH replacement should be initiated with a low daily dose, and thereafter dose-titrated according to age-adjusted serum IGF-1 concentrations and the clinical response. A higher starting dose and a faster dose titration can be used in the young. The reason is that young patients, particularly young women using oral estrogen, are less sensitive to GH and, therefore, less prone to develop dose-related side effects such as arthralgia, muscle stiffness, and peripheral edema caused by the salt- and water-retaining effects of GH and IGF-1. Typically, the dose titration takes 3 to 12 months, depending on the patient's sensitivity to GH. Because many adults with GH deficiency have a baseline serum IGF-1 that is already in the low-normal range, the target is usually a serum IGF-1 concentration in the high-normal range. Once a stable dose has been reached, IGF-1 should be measured once or twice yearly, at the same time as the clinical response, side effects, and safety are evaluated, including the effect on glucose metabolism.

Both randomized controlled trials and open longitudinal studies have demonstrated various beneficial and sustained effects of GH replacement in adults.[71,72] The most robust effects are on body composition, with reduced fat mass, in particular reduced abdominal fat, increased lean body mass, and increased extracellular water, (i.e., changes toward a normal body composition). GH has also positive effects on bone mineral density. After a temporary reduction during the first year after treatment is started, bone mineral density gradually increases.[73] Other beneficial effects are increased muscle mass and muscle strength,[74] as well as increased cardiac output and exercise capacity,[42,75] (i.e., effects that probably explain the self-reported increase in energy level, vitality, and well-being). In a prospective randomized crossover trial, quality of life improved during GH replacement, as reported by both the patients and their partners.[76] In another placebo-controlled trial where adults receiving chronic GH replacement for more than 10 years were randomized in a blinded fashion to either receive placebo or continued GH replacement, quality of life deteriorated during placebo treatment.[77]

The safety with GH replacement has been extensively studied, showing that the risk for *de novo* cancer or recurrence of an underlying pituitary tumor and cardiovascular risk is not increased.[78] Although an increased risk for developing diabetes mellitus during the initial phase of GH replacement was found in one study, other studies have not shown an increased risk. Diabetes is, therefore, not considered to be a contraindication for GH treatment. Similarly, having a residual pituitary tumor after surgery is not a contraindication, and tumor surveillance should not be influenced by treatment with GH.

One of the obstacles with GH is the daily subcutaneous injections that some patients consider unappealing and prevent them from initiating treatment. Although treatment adherence is high during the first year of treatment, it decreases markedly thereafter, with negative effect on outcome. Long-acting GH products allowing once-weekly injections have therefore been developed, mainly to improve convenience for the patients, increase the number of patients willing to start GH replacement, and improve adherence during long-term replacement.[79] Currently available data indicate that the efficacy and safety profile of long-acting GH is similar to daily GH injections.

Childhood-Onset Growth Hormone Deficiency in Adults

Approximately 10% to 20% of adults with GH deficiency are diagnosed during childhood. The main aim of GH replacement during childhood is to obtain normal growth rate and normal final height. In children with coexisting deficiencies of other pituitary hormones, careful glucocorticoid and thyroid hormone replacement is mandatory, as well as careful puberty induction, to obtain normal final height. When final height has been reached, endogenous GH production should be reevaluated in all patients who have received GH replacement during childhood, as only a minority remain GH-deficient in adulthood[80] (see also Chapter 18).

How patients with childhood-onset GH deficiency should be retested depends on the underlying etiology and how high the probability of continuing chronic GH deficiency is. Patients who likely remain GH-deficient during adulthood are those who are diagnosed with severe GH deficiency during childhood, patients with two or more additional pituitary hormone deficits, patients with structural hypothalamopituitary abnormalities, patients with central nervous system tumors, or patients who have received high-dose cranial irradiation, as well as patients with well-defined genetic causes. Reevaluation in patients with high probability of chronic GH deficiency can be performed by discontinuing GH replacement for a month and thereafter measuring serum IGF-1. If the IGF-1 standard deviation score falls below –2, GH deficiency is confirmed. In patients with a low probability of permanent GH deficiency, serum IGF-1 should be measured, and a GH stimulation test should be performed. The choice of test should depend on the experience of the center and if there is a need to test the HPA axis at the same time. Subjects with continuing GH deficiency should be offered restart of GH replacement.[48-50,80]

Hormone–Hormone Interactions

Most patients with hypopituitarism require replacement therapy with two or more hormones. Some of these interact with each other, (i.e., administration of one hormone may influence the concentration of another hormones).[47,81] In many cases this can be of clinical significance, and adequate dose adjustments are required.

KEY POINTS: Hormone–Hormone Interactions

Thyroxine–Cortisol	• Treatment with thyroxine increases the metabolism of cortisol • Initiation of thyroxine replacement in patients with untreated adrenal insufficiency can therefore induce adrenal crisis
Growth hormone (GH)–Cortisol	• GH inhibits 11ß–hydroxysteroid dehydrogenase type 1 activity • Initiation of GH replacement may induce overt adrenal insufficiency in untreated patients • Glucocorticoid dose may need to be increased in patients receiving a relatively low replacement dose when GH replacement is initiated
GH–Thyroxine	• GH reduces free T4 concentrations • Presence of central hypothyroidism may first become evident after GH replacement is initiated
Estrogen–Cortisol	• Estrogen increases production of cortisone-binding globulin, and subsequently concentrations of total cortisol in serum • Basal and stimulated cortisol in serum may be falsely high
Estrogen–GH/ Insulin-like growth factor 1 (IGF-1)	• Oral, but not transdermal, estrogen replacement attenuates the IGF-1 response of GH replacement • Higher GH doses are need in women on oral estrogen treatment

PREGNANCY

Extensive structural changes occur in the pituitary gland during pregnancy, mainly because of the dramatically increased prolactin production. Consequently, a hyperplasia of the lactotropic cells occurs, and the size of the pituitary gland increases by at least 2-fold. The biochemical alterations are also substantial and must be considered when pregnant patients with hypopituitarism are being monitored.[32]

KEY POINTS: Management of Women with Hypopituitarism During Pregnancy

Adrenocorticotropic hormone deficiency	• Exclude secondary adrenal insufficiency in all women with hypopituitarism before pregnancy • Optimize glucocorticoid doses before conception • Avoid long-acting synthetic steroids like dexamethasone that are not inactivated in the placenta • Increase the glucocorticoid replacement dose in women who experience symptomatic hypocortisolemia during pregnancy • Administer stress-doses of glucocorticoids during labor and delivery
Thyroid-stimulating hormone (TSH) deficiency	• Optimize the thyroxine dose before pregnancy by clinical evaluation and by measuring free T4, which should be in the mid-upper range of normal • TSH concentrations cannot be used to guide adjustments of the thyroxine dose in women with central hypothyroidism • Consider 25% increment of the thyroxine dose when pregnancy has been confirmed • Measure free T4 concentrations every 4–6 weeks and adjust the thyroxine dose when needed according to clinical findings and pregnancy-specific reference intervals
Growth hormone (GH) deficiency	• The safety of GH replacement during pregnancy has not been studied sufficiently • Available observations have, however, not demonstrated any difference concerning complications, or number of live births, in women who continue with GH during the first and second trimester, or throughout pregnancy, compared with those who discontinue • Based on the physiologic GH placental production, continued GH replacement should be considered during the first trimester, gradual tapering of the dose during the second trimester, and discontinuation thereafter

Serum concentrations of (total) cortisol increase during pregnancy, mainly because of the estrogen-driven increased production of corticosteroid-binding globulin.[82] Measurement of cortisol in serum has therefore a limited value in the diagnostic work-up of pregnant women suspected to have adrenal insufficiency. Concentrations of urinary free cortisol increase as well, indicating a slightly increase endogenous production during pregnancy. Nevertheless, most women with secondary adrenal insufficiency do not have to increase their regular glucocorticoid dose during pregnancy. However, some women may experience symptomatic hypocortisolemia, most commonly during the third trimester, where the dose should be increased, in particular in women on low daily doses. Long-acting synthetic steroids that are not inactivated by placental 11β–hydroxisteroid dehydrogenase type 2, like dexamethasone, should be avoided during pregnancy. Instead, short-acting glucocorticoids such as hydrocortisone are preferable. During labor and delivery, all women should receive stress-doses of glucocorticoids.

Human chorionic gonadotropin (hCG) increases during pregnancy. The chemical structure of hCG is similar to that of TSH, which allows hCG to stimulate the TSH receptor. Therefore, during the first trimester of pregnancy, the thyroid gland is mainly stimulated by hCG, and TSH concentrations are frequently low.[82] Similarly, free T4 concentrations are often high in early pregnancy and gradually decrease thereafter. In fact, free T4 concentrations during the third trimester of pregnancy are significantly lower than in nonpregnant women. TSH concentrations cannot be used to guide adjustments of the thyroxine dose in women with central hypothyroidism. Instead, the dose should be optimized before pregnancy by clinical evaluation and by measuring free T4, which should be in the mid-upper range of normal. Because the thyroid gland in patients with central hypothyroidism is intact, and hCG is the main stimulus of thyroxine production, it is uncertain whether the dose should be increased directly when pregnancy is confirmed in the same way as in patients with primary hypothyroidism. Nevertheless, a 25% increment of the thyroxine dose in early pregnancy is a common, and most probably safe, practice.[35] Thereafter, free T4 concentrations should be measured every 4 to 6 weeks and further dose adjustments performed when needed according to clinical findings and pregnancy-specific reference intervals.

Gradually increasing amounts of placental GH are produced in the placenta throughout pregnancy.[82] Increased IGF-1 concentrations are, therefore, commonly observed in the healthy pregnant woman. GH replacement seems to be safe during pregnancy. In a prospective multicenter study on women with GH deficiency, including 173 who became pregnant, no difference concerning complications or number of live births were observed between women who continued with GH throughout pregnancy compared with those who discontinued.[69] However, because data on safety are still limited, current clinical guidelines recommend that GH replacement should be discontinued during pregnancy in women with GH deficiency. Nevertheless, at some centers, based on physiologic GH placental production, GH replacement is continued during the first trimester, gradually tapered during the second trimester, and thereafter discontinued.

PATIENT CARE–MULTIDISCIPLINARY APPROACH AND PATIENT EDUCATION

To achieve the best possible treatment outcome for the individual patient with hypopituitarism, a multidisciplinary approach is necessary, including a team of experts experienced in diagnosing and treating the underlying disorder, as well as experience in managing hormone deficiencies. The majority of patients with hypopituitarism have multiple pituitary hormone deficiencies. Although some replacement therapies can be guided by serum markers such as free T4, testosterone, and serum IGF-1, the exact target for each individual patient can be difficult to determine. In addition, for other replacement therapies, such as glucocorticoid replacement, a useful biomarker for guidance of optimal dosing is lacking. Thus, adjustment of the replacement doses should be done in close collaboration between the patient and the treating physician, and symptoms of over- or underreplacement should be evaluated regularly. Indeed, patient education and increased knowledge of hypopituitarism and cardiometabolic risk factors among patients and healthcare providers, as well as the introduction of adult GH replacement therapy, are probably some of the most important explanations for the seemingly improved outcome recently reported in patients with hypopituitarism.[37,78]

Acromegaly is a disease of spectacular growth and metabolic disorders that has fascinated physicians for centuries. The natural history of the disorder, if left untreated, results in gross acral and facial disfigurement, musculoskeletal disability, cardiac failure, respiratory dysfunction, diabetes, and accelerated mortality.[1,2] If the disease occurs before epiphyseal closure, gigantism results.[1] After the first modern description of the disease in 1886 by Marie, it was subsequently recognized that the disorder is associated with a growth hormone (GH)-secreting adenohypophyseal adenoma, resulting in both a central mass lesion and the protean peripheral effects of sustained tissue exposure to high GH levels.[1,3]

KEY POINTS

- Acromegaly is usually caused by a GH-secreting pituiatry adenoma.

PATHOGENESIS

The pathogenetic events that underlie the etiology of pituitary acromegaly include excessive pituitary somatotroph cell proliferation and unrestrained GH hypersecretion (Fig. 6.1).[4] GH is secreted by somatotroph cells, the largest differentiated compartment of the anterior pituitary. GH secretion is under dual hypothalamic inhibitory control: somatotropin release–inhibiting factor (SRIF) inhibits secretion, and GH–releasing hormone (GHRH) stimulates both GH synthesis and secretion. Ghrelin, a gut-derived peptide, binds to the GH secretagogue receptor and acts primarily at the hypothalamus to induce GH release. Insulin-like growth factor 1 (IGF-1), the peripheral target molecule for GH action, participates in negative GH feedback inhibition by acting both at the hypothalamus to induce SRIF and directly at the pituitary to inhibit *GH* gene transcription.[5] Peripheral sex and adrenal steroids also regulate GH secretion.[6] GH binds to peripheral GH receptors that elicit signaling by JAK/STAT (Janus kinase/signal transducer and activator of transcription) intracellular phosphorylation cascades.[7] GH acts directly to attenuate insulin action and induce lipolysis. Most growth-promoting actions of GH are indirectly mediated by IGF-1, which is synthesized in the liver, kidney, pituitary, gastrointestinal tract, muscle, and cartilage.[7] GH actions mediated by IGF-1 include protein synthesis; amino-acid transportation; muscle, cartilage, and bone growth; DNA and RNA synthesis; and cell proliferation.[8] Local production of IGF-1 may be under autocrine and paracrine regulation, acting in concert with circulating IGF-1 and GH to elicit a final tissue impact.

Excess Growth Hormone Secretion

Tumors may arise from clonal expansion of one or more of the anterior pituitary differentiated cell types[9] and thereby result in specific hormone hypersecretory syndromes.[10] The most common cause of acromegaly is a somatotroph (GH-secreting) adenoma of the anterior pituitary, which account for 30% of all hormone-secreting pituitary adenomas (Fig. 6.2). GH-secreting adenomas arise from differentiated cells secreting *GH* gene products[1,9] (Table 6.1). These cells include somatotrophs, mixed mammosomatotrophs (secreting both GH and prolactin [PRL]), or more primitive acidophilic stem cells. Regardless of their cellular origin, transformation and subsequent replication of these cells result in adenoma formation as well as unrestrained GH secretion.[1] Most patients harbor densely granulated GH cell adenomas, which are commonly encountered in older patients with indolent disease progression.[9] Sparsely granulated GH cell adenomas occur in younger patients with more aggressive disease onset and higher GH levels.[1,2,11] Mammosomatotroph cell tumors, or discrete mammotroph and somatotroph tumors, reflect the common stem cell origin of the somatotroph cell lineage. Although acidophil

TABLE 6.1 **Clinical and Pathologic Characteristics of Growth Hormone–Secreting Pituitary Tumors**

Cell Type	Hormonal Products	Clinical Features	Histologic Features
Densely granulated somatotroph	GH	Slow growing	Numerous somatotrophs with large secretory granules
Sparsely granulated somatotroph	GH	Rapidly growing Often invasive	Cellular pleomorphism
Mixed cell (somatotroph/lactotrope)	GH and PRL	Variable	Densely and sparsely granulated somatotrophs and lactotrophs
Mammosomatotroph	GH and PRL	Common in children Gigantism Mild hyperprolactinemia	Both GH and PRL in same cell, often same secretory granule
Acidophil stem cell	PRL and GH	Rapidly growing/invasive Hyperprolactinemia dominant	Distinctive ultrastructure Giant mitochondria
Plurihormonal cell	GH (PRL) with α-GSU, FSH/LH, TSH, or ACTH	Secondary hormonal products are often clinically silent Rarely hyperthyroidism or Cushing disease	Variable: either monomorphous or plurimorphous
Somatotroph carcinoma	GH	Aggressive and invasive	Rigorously documented extracranial metastasis

ACTH, Adrenocorticotropic hormone; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *α-GSU*, α-glycoprotein subunit; *LH*, luteinizing hormone; *PRL*, prolactin; *TSH*, thyroid-stimulating hormone. (Modified from Melmed S. Pathogenesis of pituitary tumors. *Endocrinol Metab Clin North Am* 1992; 21:553-574.)

stem cell adenomas secrete GH, their predominant product is PRL, thus accounting for the high incidence of hyperprolactinemic symptoms (galactorrhea, amenorrhea, infertility) initially seen in these patients. Patients with McCune–Albright syndrome also may have acromegaly, although the presence of a discrete GH-cell adenoma has been inconsistently reported in these cases.[12] Rarely, acromegaly may occur in patients with a partially empty sella. The rim of pituitary tissue surrounding the empty sella may harbor a small endocrinologically active GH-secreting adenoma not visible on magnetic resonance imaging (MRI) (i.e., <2 mm in diameter). Very rarely, ectopic GH production by pancreatic, lung, ovarian, or lymphocytic neoplasms may result in acromegaly.[13]

Excess Growth Hormone–Releasing Hormone Secretion

Excessive circulating levels of GHRH may overstimulate the pituitary and cause somatotroph hyperplasia, GH hypersecretion, and acromegaly.[14] Central overproduction of GHRH may occur in patients harboring hypothalamic hamartomas or gangliocytomas. These rare tumors are usually diagnosed by pathologic examination of a surgically resected sellar mass causing GH hypersecretion and acromegaly. Ectopic GHRH production by neuroendocrine tumors, although rare, accounts for most cases of ectopic acromegaly.

Pituitary somatotroph hyperplasia with acromegaly associated with ectopic GHRH production has been reported in more than 100 patients, and the original isolation of GHRH was from a pancreatic neuroendocrine tumor.[15] Because the peripheral features of hypersomatotropism are quite similar in all forms of pituitary and nonpituitary acromegaly, diagnosis of the etiology of the disease may be clinically challenging.

Role of the Hypothalamus in the Etiology of Acromegaly

Hypothalamic GHRH and SRIF selectively regulate *GH* gene expression and GH protein secretion. Mice bearing an overexpressing *GHRH* transgene are subject to somatotroph hyperplasia, and ultimately to pituitary adenomas.[16] In patients with neuroendocrine tumors and ectopic GHRH production, somatotroph hyperplasia and occasionally adenomas also may develop, which suggests that disordered endocrine or paracrine GHRH or SRIF action may be permissive for pituitary tumor growth.[10] GHRH signaling defects also have been identified in acromegaly. Constitutive activation of the GHRH receptor G-protein signaling unit facilitates ligand-independent induction of *GH* gene expression. This *gsp* mutation results in guanosine triphosphatase (GTPase) inactivation, with subsequent elevated cyclic adenosine monophosphate (cAMP) levels and GH hypersecretion. Excessive cAMP response element binding (CREB) protein serine phosphorylation also may account for activation of the CREB–pituitary specific transcription factor 1 signaling unit in a subset of GH-cell adenomas.[17] cAMP activation mediates both DNA damage and GH hypersecretion in these adenomas.[18]

Intrinsic Pituitary Lesions

Virtually all GH-cell adenomas arise as discrete clonal expansions of a transformed cell[19] (Table 6.2). This monoclonal origin implies that intrinsic genetic alterations account for tumorigenic initiating events and supports observations that resection of small, well-circumscribed adenomas usually results in surgical cure of GH-secreting adenomas.

Because adenohypophyseal tissue surrounding the pituitary adenoma is histologically normal, it is unlikely that multiple independent cellular growth events (e.g., generalized hyperplasia) precede adenoma formation. Increasing evidence points to complex molecular cascades accounting for the cellular progression, resulting in pituitary-cell transformation and, ultimately, tumor formation. Multistep development of pituitary acromegaly involves a spectrum of genetic alterations associated with dysregulation of cell proliferation, differentiation, and GH production[10] (see Table 6.2).

Candidate Genes in the Etiology of Acromegaly

Generally, somatic oncogene mutations have not been found in GH-secreting adenomas. Several transgenic animal models have shown that disruption of tumor-suppressor genes (including retinoblastoma [*RB*] and *p27*) results in a high incidence of pituitary tumor formation in affected mice (Table 6.3). Loss of heterozygosity (LOH) involving chromosomes 11q13, 13, and 9 occurs in up to 20% of sporadic[20] pituitary tumors. Chromosome 13q LOH occurs in proximity to the *RB* locus and was found in 13 aggressive pituitary tumors, whereas small, well-circumscribed tumors exhibit intact *RB* alleles.[21] Chromosomal instability in GH-secreting tumors is associated with chromosomal copy number variations, and these aberrations were linked to the cAMP pathway inducing GH production.[18] Germline aryl hydrocarbon receptor interacting protein (*AIP*) gene mutations occur in a subset of young patients with familial acromegaly[22,23] (see Chapter 14). Moreover, transgenic mice heterozygous for AIP inactivation develop GH-expressing pituitary adenomas with complete penetrance.[24]

TABLE 6.2 Evidence for an Intrinsic Pituitary Defect in the Pathogenesis of Acromegaly

Growth hormone (GH)-secreting adenomas are monoclonal in origin
Somatotroph hyperplasia is rarely seen in normal pituitary tissue surrounding pituitary adenomas
Successful surgical cure of well-circumscribed GH cell adenomas is achieved in >75% of patients
Generalized somatotroph hyperplasia is rare
Unrestrained GH hypersecretion occurs independent of physiologic hypothalamic feedback control
Normalization of GH pulsatility may occur after complete adenoma resection

Modified from Melmed S. Pituitary-tumor endocrinopathies. *N Engl J Med* 2020; 382:937-950.

Activating Mutations. GTPase acts to inactivate stimulatory G (Gs) proteins that induce adenyl cyclase and intracellular cAMP accumulation.[25] Missense mutations replacing residue 201 (Arg → Cys or His) or 227 (Gln → Arg or Leu), termed *gsp* mutations, result in persistently elevated ligand-independent Gs activity and constitutively elevated cAMP and GH hypersecretion. *Gsp* mutations occur in a subset of GH adenomas, with a prevalence ranging from 30% to 40% in White patients to 10% in Japanese patients with acromegaly. X-linked acrogigantism has been reported with trisomy X, associated with overexpressed somatotroph GPR101 leading to GH overproduction mediated by protein kinase C activation.[26,27]

Development of true GH-cell carcinoma with documented extracranial metastases, however, is exceedingly rare,[28,29] and classic oncogene mutations have not been observed in large series analyzed.[18] A pituitary tumor transforming gene (*PTTG*) isolated from rat GH-secreting pituitary tumor cells[30] is homologous to yeast securin, which regulates sister chromatid separation during mitosis.[31] *PTTG* overexpression results in experimental pituitary tumor formation *in vivo*. PTTG mRNA is abundant in GH-producing tumors, with more than 10-fold increases evident in larger tumors.[32] The transforming potential of PTTG indicates a role in early induction of GH cell transformation by inappropriate regulation of the pituitary cell cycle.[33] Consistent with these observations, DNA damage with chromosomal copy number variations reported in these tumors has been linked to cAMP-mediated GH overproduction.[18] More than 70% of GH-secreting adenomas exhibit features of DNA damage and premature proliferative arrest, including increased p21 and beta-galactosidase expression, all features of cellular senescence, which may underlie the invariably benign nature of these tumors.[34]

Genetic Syndromes (see also Chapter 14). Acromegaly may occur as a component of multiple endocrine neoplasia (MEN) syndromes, including the Carney complex or MEN1. The Carney complex consists of myxomas, spotty skin pigmentation, and testicular, adrenal,

TABLE 6.3 Selected Genes Associated With Molecular Pathogenesis of Pituitary Adenomas

Gene	Function	Mode of Activation or Inactivation	Clinical Context
GNAS	Oncogene	Activating, imprinting	Nonfamilial, syndromic or sporadic
CREB	Transcription factor	Constitutive phosphorylation	Sporadic
AIP	Tumor suppressor	Inactivating	Familial, syndromic
MEN1	Tumor suppressor	Inactivating	Familial, syndromic

GH, Growth hormone.

and pituitary tumors.[35] About 20% of patients with this autosomal dominant syndrome associated with chromosome 2p16 harbor GH-secreting pituitary tumors.

MEN1, an autosomal dominant syndrome, consists of hyperplastic or adenomatous parathyroid glands, endocrine pancreas, and anterior pituitary.[36] Pituitary adenomas develop in almost half these patients, with GH cell adenomas reported in about 10% of afflicted subjects. Inactivation of the *MEN1* tumor suppressor gene likely accounts for the syndrome, in accordance with Knudson's "two hit" theory, whereby both inherited allelic germline mutations and a somatic deletion are required for inactivation of both specific alleles and subsequent tumor formation.

Low-prevalence germline mutations of the *AIP* gene (located on 11q 13.3) were reported to be predisposing in a subset of patients with familial acromegaly and gigantism[22]; 15% of families with isolated familial acromegaly exhibit *AIP* mutations, and tumors are encountered with gigantism at a younger age in subjects harboring a mutation.[37,38] *AIP* has been proposed as a tumor suppressor gene for pituitary adenomas[24]; however, the clinical significance of these findings to the broad adult population harboring sporadic GH-secreting tumors remains to be elucidated, as somatic *AIP* mutations have not been reported in sporadic tumors.

Epidemiology

Acromegaly is a rare disease, and accurate assessment of its prevalence in the community has been difficult to ascertain. Data from the United Kingdom and Belgium point to an approximately 10-fold higher incidence than previously considered.[39] In the United States, an estimated 3000 new cases are diagnosed each year.[40] The mean age at diagnosis is 40 to 45 years, and its insidious onset may cause the disease to not be diagnosed until 10 to 12 years after symptom onset.[41,42] This long delay in diagnosis is often attributed to the subtle and slow onset of common symptoms, including headache, joint pains, jaw malocclusion, or mild type 2 diabetes.[43] Furthermore, this relatively long-term delay allows prolonged exposure of peripheral tissues to unacceptably elevated GH and IGF-1 levels.

DIAGNOSIS

Persistent GH hypersecretion is the hallmark of acromegaly. Excess GH stimulates hepatic production of IGF-1, which is responsible for most of the clinical manifestations of acromegaly.[44] The diagnosis is often delayed because of slow clinical progression over many years. Heightened clinical awareness may result in earlier diagnosis. Although serum GH and IGF-1 concentrations are both increased in virtually all patients with acromegaly, serum IGF-1 levels may be discordant with GH increases.[45] When acromegaly is suspected, biochemical testing is required to confirm the clinical diagnosis, and imaging techniques are used to localize the cause of excess GH secretion (Table 6.4).

Documenting Growth Hormone Hypersecretion

The diagnosis of acromegaly is confirmed by measurement of serum GH after a glucose load and by assessing levels of GH-dependent IGF-1.[3,46,47] IGF-1 levels reflect the integrated bioeffects of GH hypersecretion, and age-matched elevated IGF-1 levels are pathognomonic of acromegaly.[48]

Measurement of the serum IGF-1 concentration is the most precise screening test for acromegaly. Unlike those of GH, serum IGF-1 concentrations do not fluctuate hourly according to food intake, exercise, or sleep, but rather reflect integrated GH secretion during the preceding day or longer. Plasma IGF-I levels correlate with mean 24-hour basal GH concentrations measured every 10 to 20 minutes.[49] Serum IGF-1 concentrations are elevated in virtually all patients, thus providing excellent discrimination from subjects without acromegaly. In normal subjects, serum IGF-1 concentrations are highest during puberty and decline gradually thereafter; values are significantly lower in adults older than 60 years than in younger subjects. Females have higher levels than males, and pregnancy may also be associated with elevated IGF-1 levels.[8] Thus, an inappropriately controlled "normal" IGF-1 value in an elderly male patient may in fact be truly elevated and indicative of acromegaly.

TABLE 6.4 Diagnosis of Acromegaly

Although all patients have increased GH secretion, it may be difficult to distinguish elevated random GH levels from normal. As GH levels fluctuate widely throughout the day and night, measuring random GH levels rarely provides useful information for diagnosis of the disorder. Short-term fasting, exercise, stress, and sleep are associated with elevated GH, and the availability of ultrasensitive GH assays has indicated that this pulsatile GH rhythm may occur at levels below the detectable sensitivity of previously available assays. Serum GH concentrations fluctuate widely, from less than 0.5 ng/mL (with ultrasensitive assays) during most of the day to as high as 20 or 30 ng/mL at night or after vigorous exercise. Random serum GH concentrations may be elevated in patients with uncontrolled diabetes mellitus, liver disease, and malnutrition, so dynamic tests have been proposed to confirm pituitary GH hypersecretion.[46]

The diagnostic hallmark of excess GH hypersecretion is failure to suppress GH levels to 0.4 μg/L or less (using a chemiluminescent immunoradiometric assay) during a 2-hour period after a 75-g oral glucose load.[46] Several factors determine measured serum GH values, including age, sex, body mass index (BMI), and the type of assay employed. Spontaneous GH secretion is attenuated by 50% to 70% in subjects aged 65 years or more, and IGF-1 levels also decline progressively with age. GH levels correlate inversely with BMI, and lean subjects exhibit higher GH values, as do female subjects. Accordingly, criteria for the diagnosis of acromegaly requires demonstrating a mean 24-hour GH level of greater than 2.5 μg/L, a nadir GH of greater than 1 μg/L after a glucose load, and/or an elevated age- and sex-matched serum IGF-1 level.

When nadir GH was measured during a 75-g oral glucose tolerance test (OGTT) in 46 acromegaly patients using three different commercial assays, GH concentrations were shown to be dependent on the specific assay employed, sex, age, and BMI.[50] Values obtained with one commercial assay were approximately 2.3-fold higher than those determined using a second assay. In one assay, postglucose values of less than 1 μg/L were associated with disease control, whereas with the other assay, the proposed cutoff value was 0.5 μg/L. Thus, interpretation of biochemical control should also be determined by knowledge of the specific GH assay employed, as well as the appropriateness of assay controls. About 10% of patients or fewer may have apparently "normal" GH or IGF-1 levels or both at the time of diagnosis. Repeating the assays in a reputable laboratory may often resolve an apparent clinical/biochemical discordance.

Localizing the Source of Excess Growth Hormone

Once a biochemical diagnosis of GH hypersecretion is confirmed, MRI of the pituitary to localize the source of hormone excess is indicated. MRI effectively delineates soft-tissue pituitary masses, and gadolinium-enhanced MRI may detect adenomas 2 mm in diameter. In about 75% of patients, the tumor is a macroadenoma (tumor diameter of >10 mm) and may extend to parasellar or suprasellar regions or invade the cavernous sinus. More than 90% of patients exhibit a discrete pituitary adenoma on MRI, whereas about 10% of patients may harbor a partial or even apparently total empty sella. Functional GH-secreting adenomas may arise in the remnant rim of pituitary tissue surrounding the empty sella and may not be visible on MRI. Rarely, other nonpituitary causes of acromegaly (see earlier) will require abdominal or chest imaging to localize the source of ectopic GHRH or, more rarely, GH production.

Nonpituitary Acromegaly. Rare nonpituitary causes of acromegaly include a hypothalamic tumor secreting GHRH,[14] a nonendocrine tumor secreting GHRH,[15] or ectopic GH secretion by a nonendocrine tumor.[13,51] If pituitary MRI findings are normal, abdominal and chest imaging should be performed, followed by catheterization studies in an attempt to demonstrate an arteriovenous GHRH gradient over the suspected tumor bed. In patients with ectopic GHRH secretion, serum GHRH and GH concentrations are both elevated, and pituitary MRI reveals a normal-sized or enlarged hyperplastic gland.[52]

An algorithm for the diagnostic evaluation of patients suspected of having acromegaly is shown in Fig. 6.3. A normal age-controlled serum IGF-1 concentration is strong evidence excluding the diagnosis. If the serum IGF-1 concentration is high (or equivocal), serum GH should be measured over 2 hours after oral glucose administration. If pituitary MRI fails to reveal the presence of a discrete adenoma in the presence of clear-cut biochemical evidence of hypersomatotropism, studies to identify the rarely encountered GHRH- or GH-secreting tumors should be undertaken.

Clinical Manifestations

The somatotroph adenoma itself, especially if a macroadenoma, may cause local symptoms such as headache, visual-field defects (classically bitemporal hemianopia), and cranial-nerve palsies. These compressive features are not unique to acromegaly and may occur with any enlarging sellar mass. Nevertheless, the headache associated with acromegaly is uniquely debilitating and may not be exclusively caused by pressure effects.

The systemic clinical features of acromegaly occur as a consequence of the deleterious impact of elevated serum concentrations of both GH and IGF-1 on peripheral tissues (Table 6.5). The somatic impact of elevated GH includes growth stimulation of a variety of tissues, such as skin, connective tissue, cartilage, bone, and many epithelial tissues, including mucosal surfaces.[3,4,53] The metabolic effects of excess GH include nitrogen retention, insulin antagonism, and enhanced lipolysis.[54]

KEY POINTS

- High levels of GH and IGF-1 lead to acral and metabolic dysfunction.

The onset of acromegaly is insidious, and disease progression is usually slow. At diagnosis, about 75% of patients are shown to harbor macroadenomas (tumor diameter of >10 mm), and some tumors extend to the parasellar or suprasellar regions.[55] Headaches are the initial symptom in approximately 60% of patients, and 10% have visual symptoms. Disease persistence is adversely determined by sparse GH tumor granularity, younger age of onset, larger and more extrasellar tumor mass extension, and higher initial GH and IGF-I levels.[11]

Acral Overgrowth. Acral and soft-tissue overgrowth is invariably a feature of acromegaly. Characteristic findings include an enlarged, protruding jaw (macrognathia) with associated mandibular overbite and enlarged, swollen hands and feet, resulting in increasing shoe and glove size and the need to enlarge rings. Facial features are coarse, with enlargement of the nose and frontal bones, as well as the jaw; the upper incisors are consequently spread apart. Despite the prominence of these findings, the rate of change is so slow that patients may not seek care because their appearance has changed. Automated facial classification photographic software has also been employed to detect the disorder.[54]

Rheumatologic Features. Musculoskeletal symptoms are leading causes of morbidity and serious functional disability in patients with acromegaly.[56] At least half of all patients exhibit minor arthralgias, and severe, debilitating arthritic features may ultimately develop. The pathogenesis of joint disease generally begins with a noninflammatory osteoarthritic disorder and culminates in severe secondary joint and cartilage degeneration.[57-59] Excess GH and IGF-1 exposure leads to uneven cartilage proliferation that results in a mechanically unstable joint surface. Subchondral cysts and osteophytes then develop in an irreversible self-perpetuating process. Severe physical deformity and functional disability result from these inexorable pathologic and mechanical stresses. The incidence of vertebral fractures is increased, approximately 40% in active acromegaly, especially in the face of lowered bone mineral density.[58,60] Hypogonadism and decreased femoral neck bone mineral density are significant risk factors. Although symptomatic and functional relief of arthritic disorders is observed in most patients after reducing GH levels, structural changes are not reversible.

Skin and Soft Tissues. The skin thickens, and multiple recurrent skin tags may appear. Hyperhidrosis at rest is common (present in 50% of patients)[2,61] and often malodorous. Hair growth increases, and some women have hirsutism. Other manifestations of soft-tissue overgrowth include macroglossia, deepening of the voice, and paresthesias of the hands (carpal tunnel syndrome) from nerve entrapment.[62,63] A symmetric sensorimotor peripheral (rarely hypertrophic) neuropathy may also occur unrelated to entrapment. Skeletal muscle mass was unchanged from controls in 27 acromegaly patients undergoing dual-photon x-ray absorptiometry.[64]

Thyroid. Thyroid enlargement may be diffuse or multinodular. Thyroid function is, however, usually normal.

Cardiovascular. Impaired cardiovascular function is an important determinant of morbidity and mortality,[3,65] with exacerbated cardiovascular risk factors.[66] The deleterious direct impact of excess GH and IGF-1 on the heart, as well as the effect of hypertension, which is present in 30% of patients, contribute to the disorder.[62,67] The severity of the cardiomyopathy correlates with the duration of exposure to hypersomatotropism. Mean left ventricular mass may be significantly increased to more than 200 g, as opposed to a normal mean weight of 140 g, and end-systolic and diastolic volumes are attenuated. Concentric ventricular hypertrophy is associated with interstitial fibrosis and lymphocytic infiltration. Resting diastolic blood pressure and left and right ventricular peak filling rates are elevated. Postexercise systolic and diastolic blood pressure may also be elevated, and the left ventricular ejection fraction is attenuated. GH induces distal nephron epithelial sodium channel–mediated sodium transport, likely accounting for the enhanced sodium retention characteristic of acromegaly.[68]

Sleep Apnea. Peripheral airway obstruction caused by macroglossia, mandible deformation, mucosal hypertrophy, and inspiratory laryngeal collapse has long been recognized as causing airway obstruction snoring, and sleep apnea.[67,69,70] Sleep apnea afflicts most patients with acromegaly and has been documented in up to 80% of cases.[71] Macroglossia and enlargement of the soft tissues of the pharynx and larynx lead to obstructive sleep apnea in about 50% of patients; others have central sleep apnea, possibly resulting from altered central respiratory control.[72] Sleep apnea may be an important cause of mortality in these patients. A central form of sleep apnea was recognized in

acromegaly[72] that appears to correlate more closely with elevated GH and IGF-1 levels and may reflect central respiratory suppression caused by the dysregulated hypothalamic–GH axis. Disease control improves or abrogates sleep apnea, with improved indices for apnea, hypopnea, and oximetry after treatment.[69,73] After 6 months of treatment of 14 apneic acromegalic patients with octreotide, a 40% decrease in the number of apneic events per hour was seen, as well as a decrease in total apneic time from 28% to 15%. Maximum oxygen saturation rose from 76% to 84%, accompanied by a decline in daytime sleepiness, as well as improvement in central and obstructive apneic parameters.[72] Nevertheless, sleep apnea may persist despite acromegaly control, and posttreatment evaluation is still required.[71]

Diabetes. GH is a potent antagonist of insulin action. Approximately 25% of patients have frank diabetes at diagnosis, and glucose values greater than 200 mg/dL (11 mmol/L) on OGTT in those without a

TABLE 6.5 Risk of Long-Term Exposure to Elevated Growth Hormone Levels

Arthropathy
Unrelated to age at onset or to growth hormone (GH) levels
Usually occurs with acromegaly of long duration
Reversibility
  Rapid symptomatic improvement with treatment
  Irreversible bone and cartilage lesions
Bone Disorders
Vertebral fractures
Neuropathy
Peripheral nerves affected
  Intermittent anesthesias, paresthesias
  Sensorimotor polyneuropathy
  Impaired sensation
Reversibility
  Onion bulbs (whorls) do not regress with lowered GH levels
Cardiovascular Disease
Cardiomyopathy
  Left ventricular diastolic function decreased
  Left ventricular mass increased; arrhythmias
  Fibrous hyperplasia of connective tissue
Hypertension
  Exacerbates cardiomyopathic changes
Reversibility
  May progress even with normalized GH levels
Respiratory Disease
Sleep apnea
  Caused by soft-tissue overgrowth and decreased pharyngeal muscle tone
Reversibility
  Improved with reduction of GH levels
Malignancy
Increased risk of soft tissue tumors and perhaps malignancy
Increased colon polyps
Reversibility
  Effect of therapy on risk of malignancy unclear
Carbohydrate Intolerance
Occurs in one fourth of acromegalics, more often with family history of diabetes mellitus
Reversibility
  Improves with reduced GH levels

Modified from Melmed S, Dowling RH, Frohman L, et al. Acromegaly: consensus for cure. *Am J Med.* 1994; 97:468.

diabetes diagnosis are not uncommon.[74] Diabetes is an important systemic complication of hypersomatotropism and a major determinant of mortality, with only 30% of patients with diabetes at the time acromegaly is diagnosed surviving 20 years.[75]

Gonadal Function. Women may have amenorrhea, with or without galactorrhea, and some have hot flashes and vaginal atrophy. Men may have erectile failure, loss of libido, decreased facial hair growth, and testicular atrophy. Hypogonadism is caused either by hyperprolactinemia (present in about 30% of patients) or by impaired gonadotropin secretion as the expanding pituitary tumor compresses normal pituitary gonadotroph cells. Asymptomatic, reversible prostatic enlargement also is common, even in men with hypogonadism.

Neoplasms. Acromegaly is associated with an enhanced risk for development of colonic polyps, as evidenced by retrospective studies,[76] whereas prospective studies have reported premalignant adenomatous colonic polyps in up to 30% of patients. Colon length is increased, and apoptotic activity is decreased. Multiple adenomatous polyps are more likely, as well as polyps proximal to the splenic flexure, underscoring the need for full-length colonoscopy.[77] Although a metaanalysis suggests a doubling of colon cancer risk in acromegaly,[78] the relationship between excess cancer-related mortality and serum GH levels is less clear.[79,80] Screening for colorectal and thyroid cancer is recommended as for the general public.[70]

Laboratory Findings

Patients exhibit increased serum GH and IGF-1 concentrations and may have hyperglycemia, with frank diabetes occurring in 25% of patients. Some patients have hypertriglyceridemia. Hypercalciuria and hyperphosphatemia (>5.5 mg/dL) occur in approximately 70% of patients as a result of direct stimulation of renal tubular phosphate reabsorption by IGF-1. Hyperprolactinemia occurs in about 30% of patients and may be caused by cosecretion of PRL and GH by the tumor or may be due to stalk interference with hypothalamic-pituitary portal delivery of dopamine. Secretion of other pituitary hormones, especially gonadotropins, also may be decreased because of mass compression.

KEY POINTS

- If uncontrolled, the disorder is associated with increased morbidity and mortality, mainly from cardiovascular, respiratory, and metabolic disorders.

Mortality

The overall mortality rate in acromegaly is about two to four times that of the general population.[81,82] In a metaanalysis of 16 studies, the overall weighted mean standardized mortality ratio (SMR) was 1.72.[83] Even after tumor surgical resection, mortality remained high (SMR 1.32).[83] Survival is reduced an average of 10 years in comparison to age-matched controls. When 18 studies of mortality outcomes in acromegaly were analyzed,[81] there appeared to be a 1.9-fold increase over expected mortality rates (range 1.16 to 3.3) for patients having undergone heterogeneous treatments. Although long-term standardized mortality outcomes have not been reported for untreated acromegaly, several significant mortality determinants are evident. These include GH greater than 2.5 μg/L, or elevated IGF-1 level, the prior use of radiotherapy, time delay from diagnosis, duration of the disease, and the presence of hypertension.[84] Most significant predictors of survival include a postglucose GH level of less than 1 μg/L, a random serum GH of less than 2 to 2.5 μg/L, or a normal serum IGF-1 level (Fig. 6.4). Clearly, attaining tight biochemical control should therefore be a goal of therapy. Aggressive management of comorbidities including hypertension, heart failure, sleep apnea, and diabetes likely also contributes to improved mortality rates.[82,85] Retrospective studies indicate that survival may be normalized to a control age-matched rate by controlling GH levels; in particular, serum IGF-1 standard deviation score life-table analysis showed that GH levels less than 2.5 μg/L were associated with survival rates equal to those of the general population.[82] A metaanalysis of 18 studies showed that controlling random GH levels to less than 2.5 μg/L and normalizing IGF-I levels restored adverse SMR to 1.1 (95% confidence interval [CI]:0.9–1.4).[86] Tight control of GH through aggressive multimodal therapy appears to reduce mortality risk to that expected for control subjects.[46]

MANAGEMENT

Treatment Goals

Treatment goals embody principles that apply to treating hormonal hypersecretory tumors (Table 6.6). Treatment should be both safe and efficacious. GH and IGF-1 levels should be normalized, especially

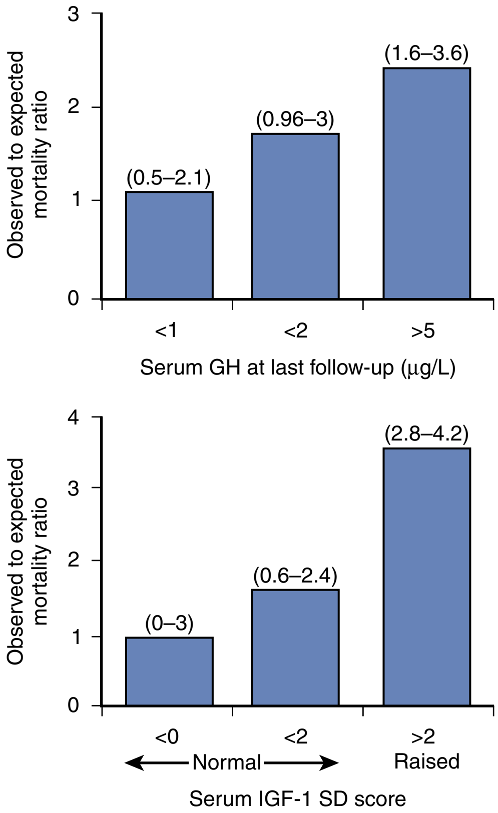

Fig. 6.4 Growth hormone and insulin-like growth factor 1 levels as mortality determinants. *GH,* Growth hormone; *IGF-1*, insulin-like growth factor 1; *SD*, standard deviation. (Data from Holdaway IM, Rajasoorja RC, Gamble GD. Factors influencing mortality in acromegaly. *J Clin Endocrinol Metab*. 2004; 89:667-674.)

because elevated GH levels have been associated with mortality in these patients. Thus, tight biochemical control is an important therapeutic endpoint. Tumor mass effects, especially central compression of visual tracts, should be alleviated. Importantly, the integrity of pituitary function should be preserved, and if hypopituitarism develops, patients require lifelong pituitary replacement. Clinical features of the disease that lead to the characteristic morbidity, and ultimately to mortality, should be ameliorated. Several treatment options are available. Transsphenoidal surgical resection of the adenoma, pharmacologic therapy with somatostatin receptor ligands (SRLs), dopamine agonists, and GH receptor antagonist (GHRA), and radiation therapy may all be used in the treatment of acromegaly. The challenge of tight GH control can now be met with greater stringency by using single or multimodal forms of therapy. Effective disease control should thus include sustained hormone suppression, a contained adenoma mass, improved systemic morbidity, and ultimately, normalized mortality (see Table 6.6).

KEY POINTS

- Treatment options include surgical excision, medical therapies, and radiotherapy.

Surgery

The most important determinant of a successful surgical outcome is the experience of the surgeon. Endoscopic approaches to pituitary adenoma resection are efficacious and safe.[87-90] Surgery rapidly alleviates acromegaly symptoms, removes the tumor mass, relieves optic-tract pressure effects, and relieves headache. Tumor debulking, even if partial, also may be helpful in enhancing the effectiveness of subsequent therapy. Surgical control also is inversely correlated with initial tumor invasiveness and GH levels.[91,92] Not all patients are appropriate surgical candidates, usually because of coexisting cardiovascular and pulmonary disease, which may be a contraindication to anesthesia. If the tumor is sufficiently large or invasive and portends intraoperative

damage to vital structures, the benefits of the procedure should be weighed against surgical risks.

Remission (defined as normal IGF-1 and either GH <0.4 ng/mL during an OGTT, or random GH <1 ng/mL) was achieved in all 14 microadenoma patients and 28 of 46 macroadenoma patients in one series.[89] Using remission criteria of normalized IGF-1 levels or GH suppression to less than 2 μg/L after glucose loading, more than 90% of patients with microadenomas successfully achieve control. Unfortunately, most tumors encountered at diagnosis are large macroadenomas, and fewer than 50% of patients with macroadenomas are biochemically controlled. For patients with these invasive tumors, surgical resection is invariably followed by persistent GH and/or IGF-1 hypersecretion. In patients with persistent disease, even after adjuvant irradiation or medical therapy, mortality remains significantly increased (almost 2-fold). Thus, the level of GH attained postoperatively is the most important determinant of mortality outcome. GH levels obtained 24 hours after surgery showed the highest predictive power for long-term remission, which was sustained in 125 of 127 patients with early GH levels less than 1 μg/L.[93] Regardless of the treatment mode, normalization of GH restores mortality risk to that of age-matched population controls, whereas postoperative disease persistence is associated with a 3.5-fold relative mortality risk.[82] Surgical debulking may improve subsequent disease control by SRLs.[94] Surgical resection of at least 75% of the tumor mass appeared to enhance responsiveness of residual adenoma tissue to postoperative SRL treatment.[95]

Surgical success is based largely on the skill and experience of the neurosurgeon and on tumor size or invasiveness. Surgery is useful for prompt reduction of GH levels, and tumor debulking may enhance the effectiveness of medical therapy. After apparent successful resection, however, up to 8% of tumors recur within 10 years. GH levels should be measured in the immediate postoperative period; evidence of GH hypersecretion at this time portends either disease persistence or long-term recurrence. Overall, for all tumor types, and using a highly sensitive immunoradiometric GH assay, postglucose GH values less than 1.0 μg/L are found in 50% of patients after surgery, whereas in 39% of patients with normalized IGF-1 levels, GH levels still fail to achieve suppression.[96]

Side Effects. The most important adverse surgical event is failure to totally resect invasive tumor, with consequent persistent hormonal hypersecretion. Postoperative complications occur in approximately 10% of patients, and their incidence is largely dependent on the experience of the operating surgeon. Complications include permanent diabetes insipidus, cerebrospinal fluid leaks requiring repair, meningitis, severe sinusitis, and hypopituitarism.[89] Perioperative morbidity and residual pituitary failure remain of concern in patients with invasive tumors, especially when operated on by less-experienced surgeons.

Pituitary Irradiation

Techniques for pituitary radiotherapy include external radiation with either a cyclotron or a cobalt-60 source. Maximal tumor irradiation with minimal damage to nontumorous surrounding tissue has been achieved by advances in stereotactic MRI-directed tumor localization, focused-beam direction, field-size simulation, head immobilization, and isocentral rotational techniques.

Tumor growth is invariably arrested after fractionated radiotherapy, but GH decline is slow, decreasing by approximately 20% per year. Within 18 years, 90% of patients have random serum GH concentrations lower than 5 μg/L. The degree and rapidity of GH attenuation are highly dependent on pretreatment GH levels.

Stereotactic ablation of GH-secreting adenomas by Gamma Knife radiosurgery has demonstrated improved efficacy. Over a 10-year follow-up period, approximately 50% achieve remission.[97,98] Proton-beam therapy also decreases GH secretion but is not widely available.

Side Effects (see also Chapter 16). Pituitary failure develops in approximately 50% of patients undergoing radiation therapy by 10 years and requires thyroid, gonadal, or adrenal steroid replacement or a combination of these.[99] Rarely, optic-tract damage results in visual deficits. Ten years after conventional radiotherapy, patients have a small risk of a secondary brain malignancy. Radiation may rarely induce brain parenchymal changes manifested as depression, decreased memory, loss of vision, and cranial-nerve palsies. Gamma Knife radiosurgery is associated with fewer local side effects. Metaanalyses show visual deficits in 3% of patients and hypopituitarism in 27%.[97] The risk for stroke and vascular injury is enhanced (SMR 4.42) in patients undergoing pituitary radiotherapy, with dosage being an adverse determinant.[100]

Thus, radiotherapy is effective in acromegaly, although its benefits are dose- and time-dependent, and GH reduction is delayed by 10 to 15 years. Radiation therapy may be useful for patients with growing pituitary tumors whose condition is not controlled by surgery or who are resistant to medical therapy.

Pharmacologic Management (Fig. 6.5)

Somatostatin Receptor Ligands. Octreotide is a synthetic octapeptide analogue of native, naturally-occurring somatostatin. This 8-amino-acid analog (molecular weight 1019 g/mol) binds selectively to somatostatin receptor 2 (SST2).[101] After subcutaneous injection, octreotide is rapidly absorbed, and peak drug concentrations (5.5 ng/mL) are achieved within 24 minutes of a 100-μg injection. The plasma distribution is about 12 minutes, and the elimination half-life is 1.5 hours, as compared with 2 minutes for natural SRIF.[101] The drug inhibits pituitary GH secretion, and also directly suppresses hepatic IGF-1 production,[102] controls tumor growth, and relieves soft-tissue symptoms. Pasireotide binds predominantly to somatostatin receptor 5 (SST5) and less so to SST2.[103] Hypopituitarism does not develop during SRL treatment, because SRIF analogs bind selectively to the somatostatin receptor subtype that regulates GH secretion.[104]

Responses to Long-Term Depot Somatostatin Receptor Ligand Preparations. Long-term depot SRL preparations include octreotide long-acting release (LAR) and lanreotide, which bind predominantly to SST2 receptors, and pasireotide LAR, which binds predominantly to SST5 receptors.[105-107] Octreotide LAR and pasireotide are delivered intramuscularly, whereas lanreotide is delivered by deep subcutaneous injection. Oral octreotide capsules (OOCs) contain unmodified octreotide suspended within a lipophilic medium in an enteric-coated gelatin capsule to enable octreotide absorption via transient openings in tight junctions between intestinal epithelial cells.[108] Administration of capsules timed to meals ensures effective octreotide bioavailability.[109,110]

Fig. 6.6 depicts the pharmacokinetic response to octreotide LAR in acromegaly. Drug levels peak at about 28 days after a single injection of octreotide LAR and decrease slowly thereafter. GH levels decline after the injection and by day 14 are suppressed to less than 2 μg/L. GH suppression (as determined by measurement of integrated secretion over a 4-hour period) is sustained through day 49 and starts increasing thereafter. From the pharmacokinetic curve, it is apparent that a single injection administered every 30 days will allow GH levels to be persistently suppressed throughout the month. GH suppression appears to be sustained as long as patients receive monthly SRL injections. A metaanalysis showed that about 55% of patients overall normalize both GH and IGF-1 levels while taking SRLs[111] (Fig. 6.7). Testosterone levels and eugonadism are also restored in most hypogonadal men. Several published studies include subjects preselected for prior GH responsivity to SRLs, and a more rigorous assessment of the literature suggests an overall response rate of 40% to 50% in unselected patients.[112] SRL therapy controls tumor growth in the majority of treated patients, and continued tumor expansion while receiving these drugs has rarely been reported. A metaanalysis of 41 eligible studies showed that 53% (95%

Growth hormone receptor (*GHR*) antagonist blocks peripheral GH signaling to suppress insulin-like growth factor 1. *GHRH*, Growth hormone–releasing hormone; *GHS*, growth hormone secretagogue; *SRIF*, somatotropin release–inhibiting factor; *SRL*, somatostatin receptor ligands; *SST*, somatostatin receptor. (Modified from Melmed S. Acromegaly. *N Engl J Med*. 2006; 355:2558-2573.)

CI:45%–61%) of patients receiving SRL therapy experience a significant reduction in pituitary tumor mass.[113] Treatment with octreotide LAR resulted in 66% (95% CI:51%–74%) of patients experiencing tumor mass shrinkage. Overall, the weighted mean percentage reduction in tumor size for all SRLs was 37.4% (95% CI:22.4%–52.4%), increasing to 50.6% (95% CI:42.7%–58.4%) for octreotide LAR. Several unresolved issues remain to be determined, including the effectiveness and safety of SRL therapy in patients exhibiting optic chiasm compression, the effects of SRL withdrawal on subsequent tumor mass reexpansion, and the effect of medically-induced tumor shrinkage on subsequent surgical outcomes.[114,115] In a randomized study of 62 patients, 6 months of presurgical treatment with octreotide resulted in enhanced surgical cure rates for patients with macroadenomas. Overall, 50% of medically pretreated versus 16% of untreated patients were cured by surgery.[115] However, in another study, long-term surgical cure rates were not altered.[114]

Several biomarkers determine patient responsiveness to SRLs and have enabled disease classification for personalized therapeutic approaches.[11] Adverse determinants include higher baseline GH levels, sparse tumor GH granularity, T2-weighted tumor hyper-intensity on MRI, and low levels of tumor SST2 expression[11,116-118] (Table 6.7). Loss of specific tumor signaling molecules, including raf kinase inhibitory protein and[116] e-cadherin,[119] and germline *AIP* mutation[120] are associated with decreased octreotide responsiveness.

Extended dosing intervals (every 6 weeks) may be effective in patients well-controlled with long-acting SRL, whereas those with persistent IGF-1 elevations may benefit from higher doses and/or more frequent dosing.[46,47,121] These patients may also benefit from a switch

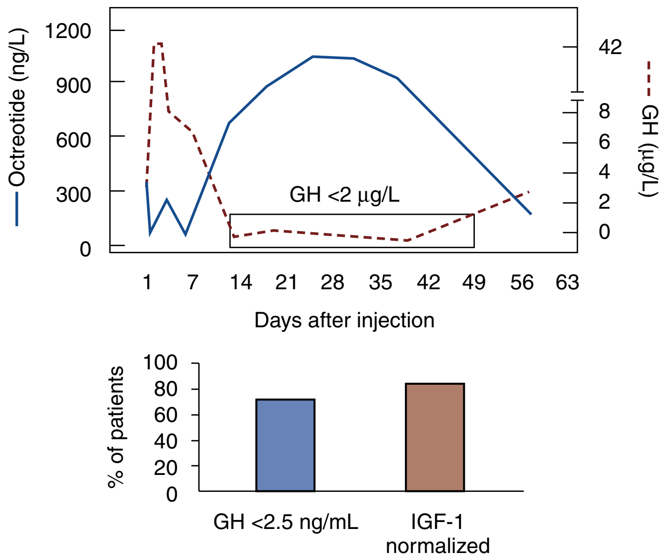

Fig. 6.6 Pharmacokinetics of octreotide long-acting release. *GH*, Growth hormone; *IGF-1*, insulin-like growth factor 1. (From Lancranjan I, Bruns C, Grass P, et al. *Metabolism*. 1996;45:67-71.)

to pasireotide,[122] but the high rate of drug-induced hyperglycemia requires careful monitoring (see later).

OOCs may be another option for patients controlled on octreotide LAR or lanreotide.[109,110] A phase 3 randomized, placebo-controlled, double-blinded study showed that 58% of patients maintained normalized IGF-1 levels after switching from injectable to oral SRL, and IGF-1 levels returned to baseline after a single SRL injection in those who required reversion to injectable SRL because of treatment failure or adverse events.[110]

OOC is initiated at a dose of 40 mg/day, but a starting dose of 60 mg/day may be an optimal starting dose for most patients.[47] Treatment is started at the time of the previously scheduled SRL injection, and can be uptitrated more frequently (every 2–4 weeks) than injectable SRLs.[47]

Side Effects. Although SRLs are relatively safe in the long term, several important adverse events have been reported. Side effect profiles are similar for all SRL formulations, except for increased hyperglycemia with pasireotide.

Asymptomatic echogenic gallbladder lesions develop in about 25% of patients.[99,101] These lesions, including sludge and gallstones, are usually diagnosed within the first 2 years of treatment, with few if any new echogenic events encountered thereafter. The prevalence of

gallstones during octreotide therapy appears to vary geographically. Dietary and/or other environmental factors play a role in their pathogenesis. Transient gastrointestinal symptoms, including anorexia, nausea, vomiting, flatulence, and loose stools, may occur, especially during the first 2 weeks of therapy; these symptoms may be ameliorated by injecting the medication between meals or at night. Rarely, fat malabsorption and bradycardia have been reported. The side effect profile of oral octreotide is not different from that of injectable octreotide.[110]

Unlike octreotide LAR and lanreotide, pasireotide is associated with high rates of drug-induced hyperglycemia, with up 40% of treated patients showing new-onset hyperglycemia and 25% developing diabetes mellitus.[122] Poor glycemic control at baseline, particularly elevated fasting blood glucose, is likely a predictive factor.[123] Treatment with antidiabetic medications ameliorates the effect in most patients, but careful patient selection and monitoring of glycemic effects are critical.[47,70]

Summary. Injectable and oral SRLs are effective and safe in managing GH hypersecretion, especially in patients in whom surgical resection has failed to achieve a stringent biochemical remission. Indications for SRL therapy include: postoperative persistence of GH secretion from residual tumor tissue; during the latency period of GH nonresponsiveness after radiation; and primary therapy of patients who decline surgery or are medically unfit for surgery or who exhibit a low probability of surgical cure.[124,125] Most patients with macroadenomas have persistent elevated postsurgical GH. Surgical debulking may enable long-term efficacy of SRLs in attaining biochemical control.[95] Oral octreotide may be particularly effective in preventing breakthrough symptoms that occur toward the end of injection cycles as injectable drug levels wane.[126,127]

Further indications that have not been verified by prospective controlled studies include the use of preoperative SRL therapy to enhance subsequent surgical results. Whether or not sustained long-term SRL therapy with or without combination with a GHRA to tightly control GH and IGF-1 levels improves ultimate mortality outcomes is not yet proven.

Dopamine Agonists. High doses of cabergoline have been used in management, but long-term results are not compelling.[128] After 18 weeks of dose titration, cabergoline did not significantly reduce mean IGF-1 levels in 24 patients and only normalized IGF-1 levels in two patients.[129] Because high doses are required to achieve even moderate efficacy, the incidence of adverse events is far higher than that usually seen when treating patients with prolactinomas. Patients receiving high doses of dopamine agonists complain of gastrointestinal symptoms, including nausea, vomiting, and abdominal cramps. Rarely, arrhythmias have been reported. Nasal stuffiness and sleep disturbances are common complaints.

Growth Hormone Receptor Antagonist. Pegvisomant, a GHRA, directly inhibits GH action in the periphery.[130] Unlike SRLs and dopamine agonists that act centrally to inhibit GH secretion through somatotroph cell somatostatin and dopamine receptors, pegvisomant interferes with GH receptor signaling, thereby suppressing peripheral IGF-1 generation in almost all patients with GH-secreting pituitary tumors treated for up to 36 months. Pegvisomant binds one GH receptor unit at site 1 but cannot bind the mutated site 2.[130] The site 2 mutation in pegvisomant blocks initiation of subsequent GH signal transduction.

In an initial study, daily doses of pegvisomant (10, 15, or 20 mg) given for 12 weeks normalized IGF-1 levels in 38%, 75%, and 82% of patients with acromegaly, respectively[131] (Fig. 6.8). Subsequent longer-term follow-up in ACROSTUDY patients monitored for 5 years reported IGF-1 normalization in 63% of patients with a mean dose of 18 mg/day.[132] Concomitant dose-dependent reduction in serum IGF-1 levels is accompanied by dose-dependent regression of soft-tissue swelling, excessive perspiration, and fatigue, with no significant improvement in arthralgias or headache. Pegvisomant also improves insulin sensitivity and glucose tolerance, reducing fasting serum insulin and glucose levels and decreasing glycated hemoglobin levels.

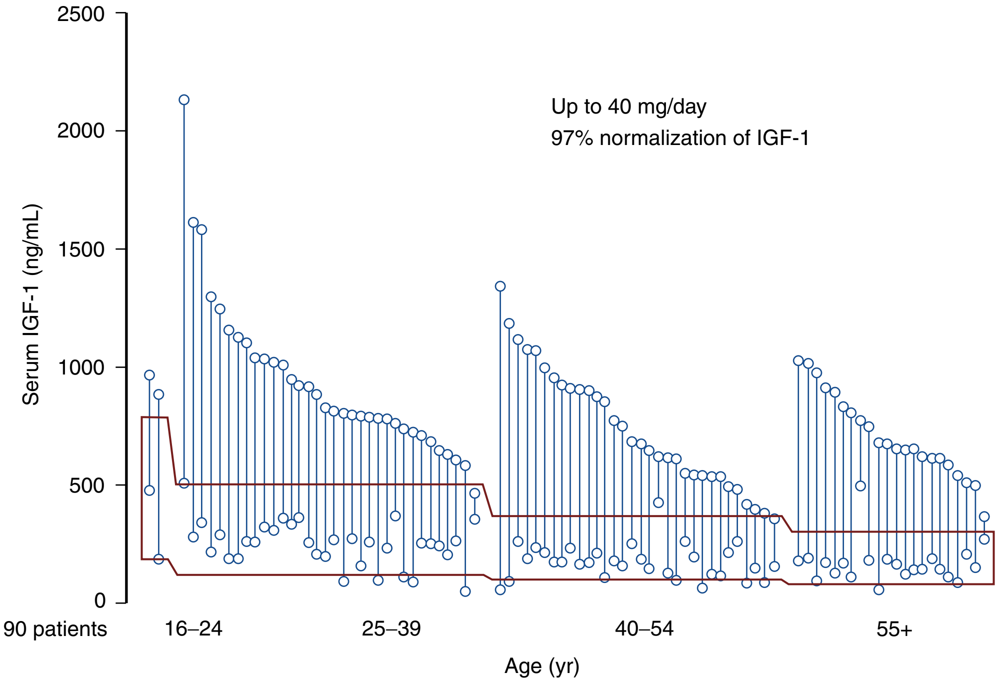

Fig. 6.8 Insulin-like growth factor 1 (IGF-1) levels at baseline and after 12 months of pegvisomant therapy. (Data from van der Lely AJ, Hutson RK, Trainer PJ, et al. Long-term treatment of acromegaly with pegvisomant, a growth hormone-receptor antagonist. *Lancet*. 2001; 358:1754-1759.)

Short-term (<3 months of treatment) side effects encountered in pegvisomant-treated patients included reversible injection-site reactions (11%) and diarrhea (14%) in an 18-month study.[133] GH levels are reversibly increased by approximately 2-fold, mirroring the IGF-1 decrease. Despite detection of anti-GH antibodies in 17% of patients, no evidence of tachyphylaxis was found. Pegvisomant also enhances insulin sensitivity in patients exhibiting glucose intolerance. In a follow-up of 1288 subjects treated for a mean of 3.7 years, serious adverse events were reported in 12% of subjects. Persistent pituitary tumor growth is observed infrequently (~3% of patients), and transiently elevated (3 times the upper limit of normal) liver transaminase levels are observed in up to 2.5% of patients, with rarely reported drug-induced hepatitis[132]. Other side effects include lipohypertrophy[134] and features of hypopituitarism if IGF-1 levels are attenuated to below normal ranges.

GH levels are elevated in patients receiving pegvisomant therapy, so IGF-1 levels are measured to monitor efficacy, emphasizing the need to standardize commercial IGF-1 assays and develop age-specific reference ranges. IGF-1 levels should be titrated to midnormal ranges. Possible overtreatment with pegvisomant may create clinical features of GH deficiency, as pegvisomant may suppress IGF-1 levels below the lower limit of normal.

Pegvisomant alone or in combination with SRL can normalize IGF-1 levels in SRL-resistant patients[46] with weekly, twice-weekly, or daily pegvisomant injections and SRL cotreatment,[135,136] and less frequent dosing may be more cost effective[137] (Fig. 6.9). Combination with cabergoline may also offer additive efficacy.[129]

INTEGRATED TREATMENT APPROACH TO THE MANAGEMENT OF ACROMEGALY

Patients With Likelihood of Good Surgical Outcome

After diagnosis, the likelihood of surgical cure is assessed. For small, well-circumscribed tumors, surgical excision by an experienced pituitary surgeon is the treatment of choice.[1] Surgical cure rates are maximal for noninvasive, well-encapsulated smaller tumors.[88,89] After surgery, patients are monitored to ensure that GH responses to a glucose load are less than 1 μg/L and that IGF-1 levels are normalized. If, however, after surgery, hormone levels are not controlled, which is indicative of disease persistence or recurrence, SRLs are indicated.[46] Pegvisomant as monotherapy or combined with an SRL is indicated after failure of other therapy. Patients should be followed by measuring age-matched IGF-1 levels, aiming for the midnormal range levels. Liver function tests should be evaluated monthly during the first 6 months of pegvisomant therapy. If the patient is still not biochemically controlled, a dopamine agonist is added, or reoperation or irradiation is considered.

Patients With a Poor Likelihood of Successful Surgical Outcome

Patients with large adenomas are likely to have a poor surgical outcome, and fewer than half will be biochemically controlled. Most newly diagnosed patients have large macroadenomas, which portend a poor surgical outcome with persistent postoperative GH hypersecretion.[92] They can be offered primary medical treatment, as would patients in whom surgery is contraindicated or those who decline surgery.[138] Use of preoperative octreotide to enhance subsequent surgical outcomes has been advocated,[115] as the drug reduces tumor bulk. If biochemical control is not achieved, drug efficacy may be improved by dose increases, use of monotherapy or combination GHRA therapy, or addition of a dopamine agonist.[46] If patients are resistant to medical treatment, second surgery or irradiation is indicated, depending on the size and location of the tumor remnant and the skill of the neurosurgeon.

KEY POINTS

- Long-term surveillance and management are required to achieve optimal control of comorbidities and mortality.

Follow-Up

Laboratory follow-up of patients includes attaining stringent responses of GH less than 1 μg/L, accompanied by a normalized IGF-1 level. If these goals are not achieved, medical treatment should be initiated. If already being administered, efficacy may be improved by increasing medication dose frequency, combining a GHRA with an SRL, using GHRA as monotherapy, or adding a dopamine agonist. Reoperation and radiation therapy are further adjuvant options for resistant patients. In patients with tumors that have been effectively excised,

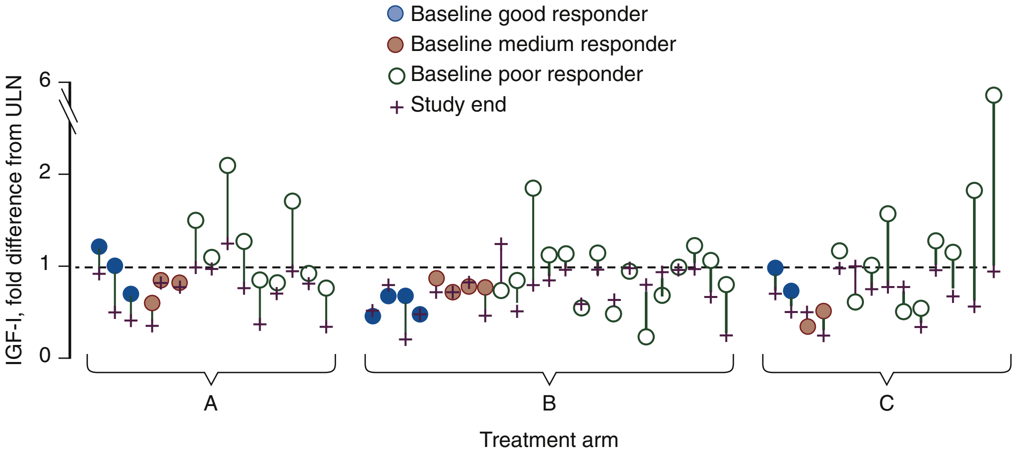

Fig. 6.9 Fold difference from upper limit of normal in IGF-1 at baseline and study end in 52 participants who completed at least 24 weeks combination SRL plus pegvisomant therapy stratified as good, medium, or poor responders to prior SRL and grouped by treatment arm. Arm A, high-dose SRL plus weekly pegvisomant; arm B, low-dose SRL plus weekly pegvisomant; arm C, low-dose SRL plus daily pegvisomant. *IGF-1*, Insulin-like growth factor 1; *SRL*, somatostatin receptor ligand; *ULN*, upper limit of normal. serial MRI is warranted only once every 2 years after surgery. Invasive residual tumor tissue mass or recurrent tumors require more frequent MRI evaluation. Although tumor mass may not invariably shrink with SRL therapy, further progressive tumor growth rarely occurs while patients are taking the medication.

Additional Management Considerations

The clinical, economic, and quality of life burden for these patients is significant, and optimizing disease control to improve adverse outcomes is imperative.[126,127,139] Patients with acromegaly require management of multiple associated comorbidities. Colonoscopy should be performed at diagnosis. Because cardiovascular morbidity is so high, aggressive management of hypertension, left ventricular hypertrophy, cardiac failure, and arrhythmias should be pursued. Pulmonary function and sleep evaluation should be undertaken in all patients early in the course of the disorder, and debilitating arthritis requires aggressive rheumatologic management. Screening and therapy for insulin resistance and diabetes are important, and SRLs usually improve diabetes control dramatically, except for pasireotide, which usually exacerbates hyperglycemia. Insulin requirements may immediately decrease to 90% of pretreatment needs as GH is effectively suppressed. Headache is an extremely common symptom and usually improves with SRLs; if not, potent analgesics may be indicated. Maxillofacial disorders may require dental, maxillary, and facial cosmetic surgery. Fertility is commonly of concern to patients, and reports of successful pregnancies in women treated with octreotide provide optimistic guidelines for pregnancy management.[140] As patients with acromegaly may be depressed and have low self-esteem and other psychosocial sensitivity,[133] individual or group counseling may be indicated. Finally, all available treatment modes for acromegaly are associated with therapy-specific complications, which, if they arise, should be promptly addressed.

Long-acting depot and oral preparations of SRLs as well as GHRA have changed the approach to management, inasmuch as efficacy, patient compliance and medication safety are attained.

Cushing syndrome consists of a group of symptoms caused by chronic and excessive tissue exposure to glucocorticoids. Given the paramount importance of glucocorticoids in the regulation of numerous physiological functions, Cushing syndrome results in the disruption of multiple homeostatic processes and is responsible for a significant clinical burden in the majority of patients, including increased mortality and impaired health-related quality of life. Despite significant advances in our understanding of the disease and improvements in sophisticated diagnostic and therapeutic tools, Cushing disease still poses many challenges, ranging from its early diagnosis to the difficulty of curative surgery and limiting the long-term sequelae, decreased quality of life, and decreased life expectancy.

EPIDEMIOLOGY

Cushing syndrome is a rare condition. The most common cause remains iatrogenic, resulting from prolonged corticosteroid therapy. From a pathophysiological standpoint, endogenous Cushing syndrome can be divided into adrenocorticotropic hormone (ACTH)-dependent and ACTH-independent causes. ACTH dependent-causes represent 70% to 82% of cases of Cushing syndrome in adults, and among these Cushing disease accounts for 86% to 93% of cases (Fig. 7.1).[1-3] Precise determination of its epidemiology is limited by the small size of studies, but the incidence of Cushing disease is estimated to be between 1.8 and 2.6/million population/year.[3,4] The incidence may have increased in the last few decades owing to increased medical awareness and refinement of biochemical diagnostic methods.[4] The prevalence of declared cases of Cushing disease in Biscaye, Spain in 1994 was 39.1 per million inhabitants.[5] The prevalence can also be estimated from community-based cross-sectional studies, regional databases and sellar mass registries, and national collections of clinically-relevant pituitary adenomas. A metaanalysis of studies conducted in geographically diverse populations[6] revealed a mean prevalence of pituitary adenomas of 89.1 per 100,000 (range: 76–116 per 100,000). Corticotroph adenomas responsible for Cushing disease accounted for 4% of these. The epidemiology of Cushing disease in children and pregnant women differs significantly from that in nonpregnant adults (see Special Conditions).

ETIOLOGY OF CUSHING DISEASE

Cushing disease is caused by tumoral proliferation of autonomously secreting pituitary corticotrophs. This proliferation depends on a

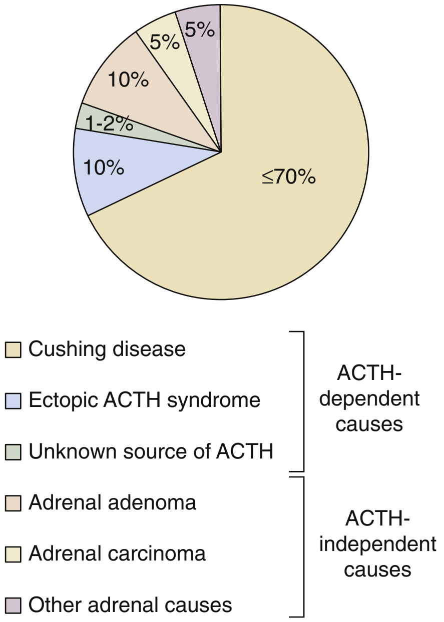

Fig. 7.1 Causes of endogenous Cushing syndrome. Approximate prevalence of the different etiologies of Cushing syndrome according to the literature. *ACTH,* Adrenocorticotropic hormone.

KEY POINTS

- Since 2014, thanks to the availability of modern exome sequencing, somatic mutations have been identified in more than half of the cases of corticotropic adenomas responsible for CD. Identifying these molecular alterations could pave the way for future medical treatments.

monoclonal expansion of cells. Although corticotroph hyperplasia has been reported in the periphery of adenomas, hyperplasia does not seem to be able, *per se,* to elicit a Cushing syndrome (apart from in the very rare context of ectopic corticotropin-releasing hormone [CRH] secretion).[1]

The fourth edition of the World Health Organization (WHO) classification of pituitary tumors takes into account cell lineage and changes in histopathology grading.[7] Applied to corticotropinomas, the classification identifies densely-granulated, sparsely-granulated, or Crooke cell adenomas.[7] Corticotropinomas are from a T-box pituitary restricted transcription factor (T-Pit) lineage, consequently showing specific T-Pit immunoreactivity. Although most corticotropinomas are small microadenomas, some are macroadenomas. Despite their rarity, corticotropinomas are the second most frequent origin of pituitary carcinomas (less than 1% of all pituitary neoplasms).[8] Two specific corticotropinomas are of particular concern for their frequent aggressive behavior: silent corticotroph adenomas and Crook cell adenomas.[7,9-11] Subsequent to the 2017 WHO classification, it has been proposed to change the nomenclature of pituitary adenomas to pituitary neuroendocrine tumors (PitNETs), to provide more uniformity in the classification of all neuroendocrine tumors despite organ-specific differences.[7] For example, investigating aggressive PitNETs using the same approach as has been used in neuroendocrine tumors (NETs), it was found that loss-of-function of the *ATRX* gene, which has been shown to predict malignant tumor phenotype in NETs, is highly prevalent in aggressive corticotroph tumors.[12]

Tumoral corticotrophs synthesize pro-opiomelanocortin (POMC) and secrete POMC-derived peptides, including ACTH, with no apparent qualitatively abnormal processing in most tumors responsible for Cushing disease. ACTH secretion in adenomas exhibits some resistance to glucocorticoid-induced negative feedback. However, no frequent gross abnormality in the glucocorticoid receptor has been demonstrated, and no clear reason for this resistance has yet been uncovered. A subset of corticotroph adenomas are characterized by the absence of Cushing syndrome and normal cortisol dynamics or elevated ACTH associated with mildly abnormal cortisol dynamics. These so-called silent corticotroph adenomas usually present as macroadenomas associated with mass-related symptoms. Various mechanisms may explain why an adenoma that synthesizes ACTH does not cause the Cushing syndrome.[13] These include polymorphisms in the *POMC* gene, predominant secretion of high–molecular weight ACTH, increased intracellular degradation of ACTH, and failure of exocytosis of ACTH from the cell membrane[13,14]: alterations in the processing of the prohormone POMC in corticotrophs is the most likely. Studies have demonstrated a huge decrease in the expression of prohormone convertase 1/3, an enzyme involved in the posttranslational processing of POMC into mature and biologically active ACTH, in silent corticotroph adenomas as compared to corticotroph adenomas associated with hypercortisolism. This abnormal processing, which has also been described in aggressive and corticotroph-secreting adenomas, may result in high circulating levels of POMC.[15] Interestingly, a subset of silent corticotroph adenomas can evolve into Cushing disease after years of inactivity, and this transformation is associated with the resumption of a robust expression of prohormone convertase 1/3.[13]

Until 2014, studies of the pathogenesis of corticotroph adenomas with hypothesis-driven molecular explorations were unsuccessful. Targeted approaches looking for gene mutations in known endocrine familial genetic disorders did not fare any better: only a minor fraction of cases of Cushing disease show alterations associated with germline mutations linked to pituitary adenomas (multiple endocrine neoplasia 1 (*MEN1*), cyclin-dependent kinase inhibitor 1B and 2C (*CDKN1B* and *CDKN2C*, associated with MEN4), and aryl-hydrocarbon receptor-interacting protein (*AIP*)).[16,17] Other potently oncogenic germline mutations of *GNAS, PRKAR1A*, succinate dehydrogenase subunits (*SDHs*), and *TSC1/2* have been occasionally described.[16,17] Disrupted microRNA production in DICER1 syndrome and germline mutations in genes associated with the mismatch repair pathway (*MLH1, PMS2, MSH2, MSH6*) leading to an autosomal dominant inherited cancer syndrome have also been rarely identified in patients with aggressively ACTH-secreting tumors.[16,17]

With the availability of high-throughput exome sequencing, seminal whole-exome studies of corticotroph adenomas identified somatic mutations in the deubiquitinase gene *USP8* in four out of 10[18] and eight out of 12 adenomas.[19] *USP8* gain-of-function mutations were confirmed by subsequent independent studies.[17] A meta-analysis of 677 patients showed that about 32% of female and 14% of male patients with corticotropinomas have a somatic *USP8* mutation.[20] Interestingly, no such mutations in *USP8* were found in other pituitary tumor subtypes. Somatic mutations in *USP8* are also common in Nelson tumors.[21] Lastly, a single case of a 16-year-old patient with a *de novo* germline *USP8* mutation with recurrent Cushing disease and multiple unrelated comorbidities was recently reported.[22]

From a pathophysiological point of view, USP8 is a deubiquitinase, that is, an enzyme that removes the ubiquitin tag that labels proteins for proteasomal or lysosomal degradation (Fig. 7.2). Phosphorylated USP8 binds to the 14-3-3 protein, in hibiting its activity. USP8 mutants fail to bind 14-3-3 protein and thus remain active. Active USP8 deubiquitinates numerous target proteins, thus protecting them from degradation. Epidermal growth factor receptor (EGFR) is an important such target in corticotrophs, stimulating POMC transcription via several pathways. Activating *USP8* mutations rescue the EGF receptor from lysosomal degradation, thus increasing both receptor expression and intracellular signaling. The demonstrated role of the EGFR pathway in *USP8*-mutated tumors presents opportunities for the use of EGFR inhibitors such as gefitinib.

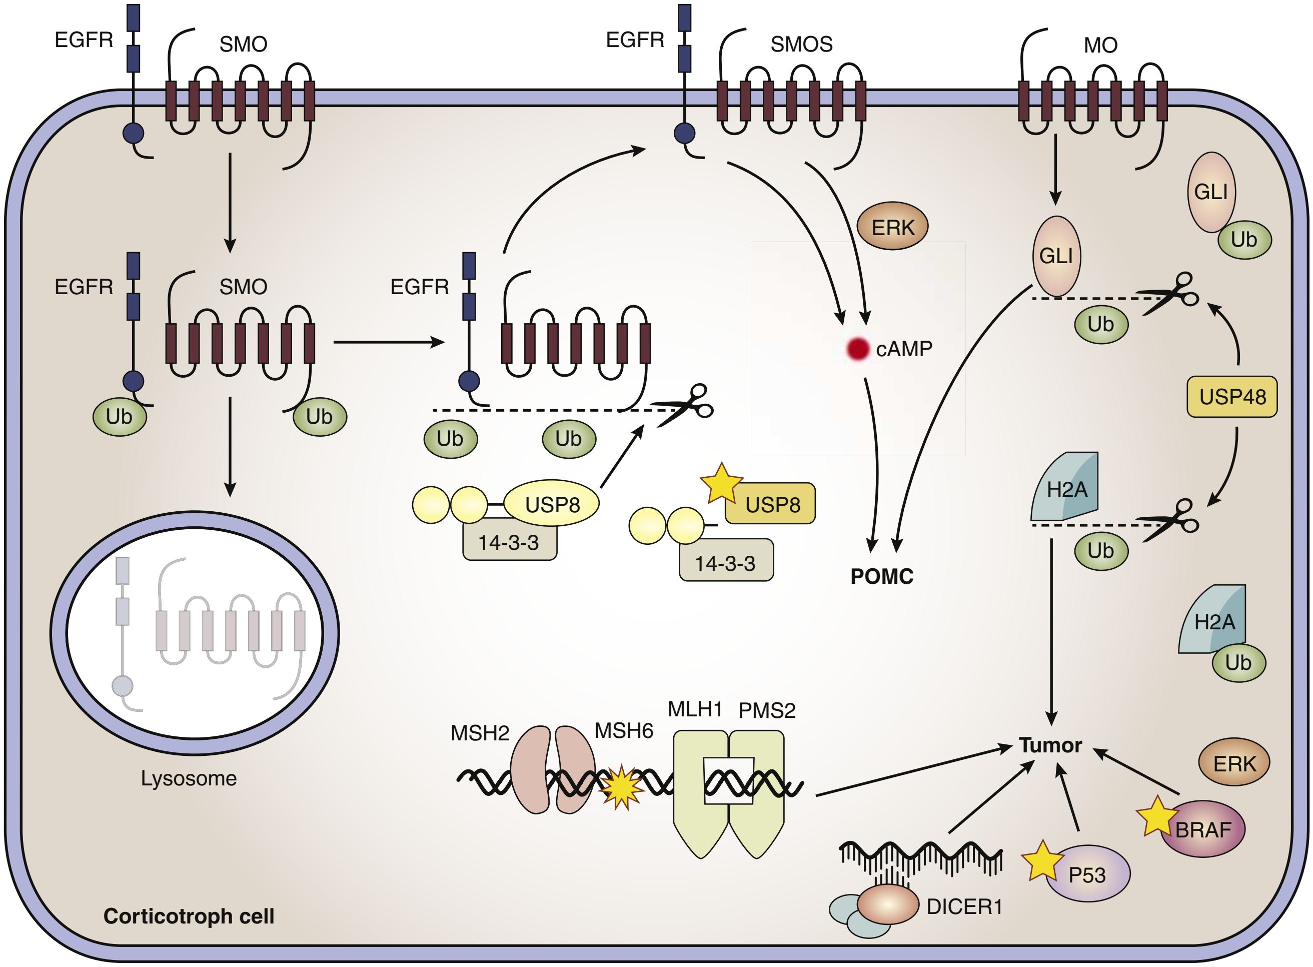

Fig. 7.2 Recurrent gene mutations found in corticotropinomas and their consequences. The deubiquitinase USP8 removes ubiquitin (*Ub*) tags from its targets, such as epidermal growth factor receptor (*EGFR*) and smoothened (*SMO*), preventing these receptors from being degraded in the proteasome and allowing them to be recycled back to the cell surface. Mutated USP8 displays increased enzymatic activity and thus leads to higher expression of the receptors on the cell membrane. Increased EGFR and SMO activity leads to increased cyclic adenosine monophosphate (*cAMP*) signaling and pro-opiomelanocortin (*POMC*) levels. Similarly, *GLI1* and *histone 2a (H2A)* may be targeted by USP48, leading to increased activity with *USP48* mutations. Loss-of-function mutations of *DICER1, TP53, MLH1,* and *MSH2* and gain-of-function mutations of *BRAF* have also been suggested to be sporadically associated with corticotroph tumorigenesis. (Reproduced with permission from Nadhamuni VS and Korbonits M. Novel insights into pituitary tumorigenesis: genetic and epigenetic mechanisms. *Endocrine Reviews.* 2020;41:1-26.)

Metaanalysis of the currently available literature concerning the genotype–phenotype correlations of *USP8* mutants reveals a number of discrepancies between series regarding the age of patients, size of adenomas, prevalence of mutations in microadenomas versus macroadenomas, intensity of ACTH and cortisol secretion, aggressiveness of adenomas, and probability of surgical failure.[20] The lack of a systematic protocol evaluating these patients and selection bias may account for this heterogeneity, preventing any definitive conclusion. Recent whole-genome studies shed new light on the characteristics of *USP8*-mutated adenomas. In a recent pangenomic analysis, *USP8*-wild-type corticotroph PitNETs appeared to be more aggressive than *USP8*-mutated PitNETs, with more frequent sphenoid invasion; this finding was supported by transcriptome analysis, which identified an increased epithelial-mesenchymal transition signature.[10] Similarly, whole-genome sequencing and genomic instability assessment of a series enriched in aggressive corticotroph tumors found that *USP8*-mutated tumors were less aggressive and less prevalent than *USP8*-wild-type tumors among silent corticotroph or Crooke's cell tumors. In accordance with this, most *USP8*-mutated tumors lack somatic inactivating *TP53* driver mutations and exhibit a nondisrupted genome.[11] Interestingly, increased somatostatin receptor 5 (*SSTR5*) expression was found in *USP8*-mutated corticotropinomas compared to their *USP8*-wild-type counterparts.[10] Whether *USP8*-mutated corticotropinomas respond better to the SSTR5 agonist pasireotide remains to be demonstrated.

Further exome-sequencing studies looking for driver mutations have revealed additional infrequent genetic alterations in corticotroph adenomas, including loss-of-function mutations of the glucocorticoid receptor gene in about 5% of *USP8*-mutated corticotropinomas.[17] Another deubiquitinase gene, *USP48*, was found to be mutated in about one-tenth to one-quarter of corticotropinomas.[17] *USP48* mutants enhance transcription of the *POMC* gene through *USP8*-independent pathways.[17] Mutations of *USP8* and *USP48* do not seem to occur simultaneously. The well-known protooncogene *BRAF* may also be mutated in approximately 12% of corticotropinomas.[17] *BRAF* activates a signaling pathway that increases POMC synthesis, and, interestingly, *in vitro* studies show that clinical BRAF inhibitors decrease ACTH production.

Loss-of-function mutations of the *CABLES1* gene were found in a small subset of patients and were preferentially associated with corticotroph macroadenomas.[17]

Mitotic count and the Ki-67 labeling index, along with radiological invasiveness, are the most commonly used markers of pathological aggressiveness in clinical practice.[9] Unfortunately, these criteria do not accurately predict pituitary tumor behavior such as rapid growth, recurrence, and malignant transformation.[7,9,17] Multiomics analysis of corticotroph PitNETs (including analysis of somatic mutations, chromosomal alterations, miRNome, methylome, and transcriptome studies) represent a hope for a better and clinical relevant classification of corticotroph tumors. Subgroups of corticotropinomas based on their transcriptome, miRNA clusters, and changes in histone acetylation that are associated with ACTH secretion, glucocorticoid resistance, and aggressiveness have already been recently identified.[10,11,17]

PATHOPHYSIOLOGY

Excessive ACTH secretion stimulates steroidogenesis in the zona fasciculata and zona reticularis of the adrenal cortex, inducing an immediate release of cortisol, aldosterone, and dehydroepiandrosterone (DHEA), and Δ-4-androstenedione via cyclic adenosine monophosphate (cAMP)-dependent pathways, as well as the expression of key steroidogenesis enzymes, Gs protein, and the ACTH receptor MC2R. ACTH also activates an autocrine network, including insulin-like growth factor 1 (IGF-1), IGF-2, basic fibroblast growth factor, and transforming growth factor β, that is responsible for bilateral adrenocortical hyperplasia and rendering the hyperplastic adrenocortical cells more sensitive to ACTH, thus further increasing the cellular response.

Although aldosterone is secreted in response to ACTH, negative feedback suppresses aldosterone synthesis. A multiplex analysis of 15 steroids showed that ACTH-driven Cushing syndrome exhibits lower aldosterone levels than are seen in cortisol-secreting adrenal adenomas.[23] However, synthesis of mineralocorticoids such as 11-deoxycorticosterone (DOC) and, in many cases, 18-OH-DOC, is increased and can contribute, along with cortisol, to an increase in blood pressure.

CLINICAL FEATURES

Clinical Aspects

Excessive cortisol production has numerous systemic effects, given the widespread expression of its receptors (Table 7.1). Although the full-blown Cushingoïd phenotype is unmistakable, clinical diagnosis may be equivocal in patients with few of the typical characteristics. These cases often correspond to patients with mild hypercortisolism or given the common slow progression of the disease, patients in whom the onset of the disease is recent (Fig. 7.3). Another difficulty is that chronic hypercortisolism is responsible for nonspecific features such as obesity, hypertension, and menstrual irregularity, which are common in the general population. This situation generates two contradictory caveats: performance of unwarranted and costly screening tests for patients unlikely to be affected (see Who Should Be Tested) and, conversely, a mean latency to diagnosis of 38 months.[24]

One useful strategy when considering the diagnosis of Cushing syndrome is to look for evidence of progressive physical changes by examining serial individual photographs taken in the past (Fig. 7.3). Another approach relies on identification of the more specific signs and symptoms of the disorder. Ecchymoses (Fig. 7.4), plethora, myopathy/proximal muscle weakness, and osteopenia/osteoporosis, as well as wide purple striae (Fig. 7.5), which reflect the catabolic and antianabolic effects of cortisol excess on protein metabolism, are associated with the highest positive likelihood ratio (Fig. 7.6).[25,26]

TABLE 7.1 **Prevalence of the Main Symptoms of Cushing Disease at Presentation**

Symptoms	Prevalence (%)
Obesity/weight gain	70–95
Rounded face (moon face)	81–90
Supraclavicular/dorsocervical fat pads	50
Skin	
Hirsutism/alopecia	56-75
Facial plethora	70–90
Violaceous striae	44–50
Easy bruising	35–65
Acne	20–35
Gonads	
Menstrual irregularity	43–80
Male hygonadism	50–75
Neuropsychological	70–85
Emotional lability/depression	54–81
Anxiety disorder/emotional lability	36–66
Sleeping disorders	57–69
Cognitive dysfunction	50–90
Musculoskeletal	
Muscle weakness/atrophy	42–83
Osteopenia or fractures	21–70
Decreased linear growth in children	70–80
Metabolic	
Hypertension	58–85
Glucose intolerance/diabetes mellitus	30–70
Dyslipidemia	38–71

Increased deposition of fat, one of the earliest signs, occurs in almost all patients and is reported as weight gain or difficulty in maintaining weight.[27] Fat distribution is altered with increased amounts in the visceral compartments and subcutaneous sites on the face and neck, resulting in the typical truncal obesity. Increased fat in the face ("moon facies"), as well as in the supraclavicular and the dorsocervical area ("buffalo hump"), is uncommon in healthy people (Fig 7.7). Although these features are common in massive obesity, this redistribution of fat is very evocative when associated with minimal weight gain and when it contrasts with thin arms and legs owing to myopathy (Fig. 7.8). Loss of subcutaneous tissue and thinning of the skin results in skin abnormalities that are rare in the general and middle-aged population. Ecchymoses (Fig. 7.4), often after minimal trauma, and cutaneous atrophy, seen as a fine "cigarette paper" wrinkling over the dorsum of the hand, are also typical (Fig. 7.4). Cutaneous atrophy is physiologically influenced by gender and age, with men and younger individuals having greater skin thickness. Therefore, it is useful to compare the patient's skin with that of a near age- and gender-matched healthy person.

Spontaneous facial plethora (e.g., in the absence of topical drying agents and glucocorticoids), especially over the cheeks, is a characteristic feature that usually decreases rapidly in intensity after cessation of hypercortisolism (Fig 7.7). Facial erythema is also related partly to loss of subcutaneous tissue and is more obvious in pale White individuals. A demarcation line, representing collar,

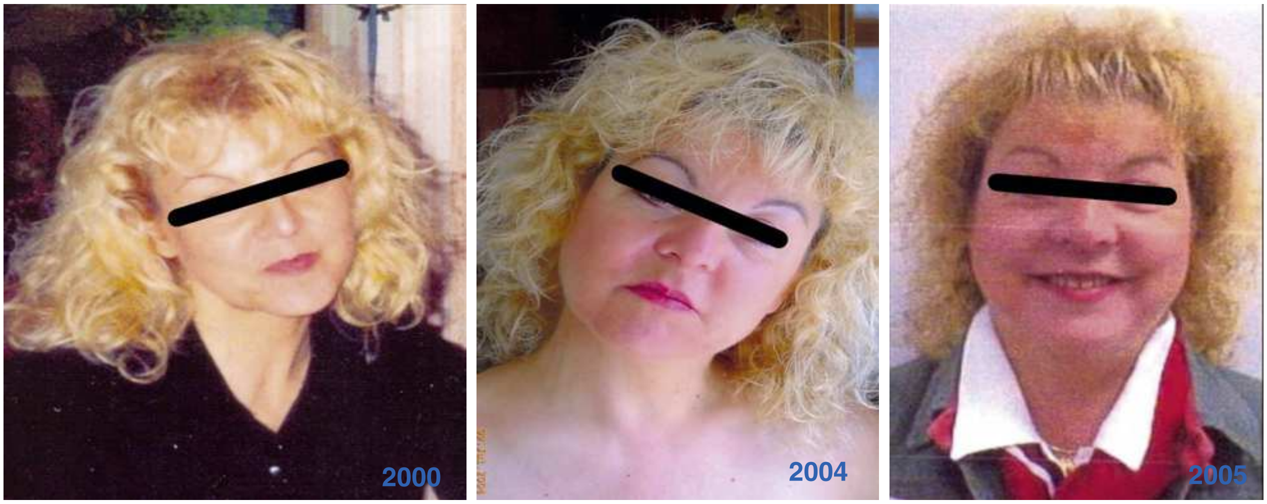

Fig. 7.3 Progression of Cushingoïd features. Note the typical slow progression of facial rounding and plethora over 5 years.

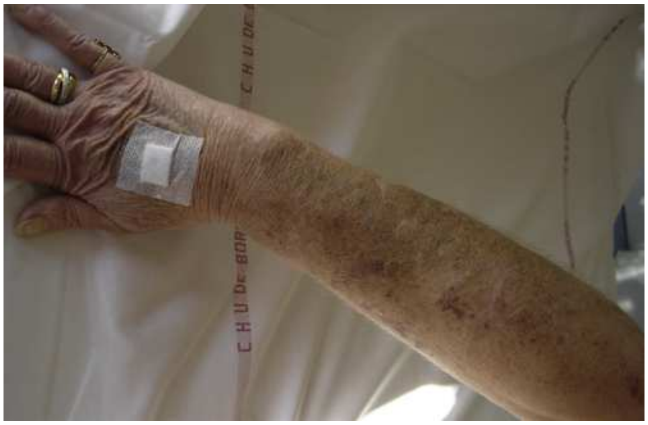

Fig. 7.4 Multiple spontaneous ecchymosis and thinning of the skin in a 63-year-old woman with Cushing disease.

sleeve, or shoulder straps, may differentiate hypercortisolism-related erythema from exogenous causes such as ultraviolet radiation from ultraviolet lamps or sunlight.

Purple striae greater than 1 cm in width are virtually pathognomonic for Cushing syndrome (Fig. 7.5) and appear very different from the silvery, healed striae that are typical postpartum. Although most common over the abdomen, striae also occur in unusual parts of the body, such as over the hips, buttocks, thighs, breasts, and upper arms.

Proximal muscle weakness is a hallmark of Cushing syndrome[28] (Fig. 7.8) and has been reported in 70% of subjects in large cohorts.[2] Histologically, this is reflected in profound atrophy of fibers, or fatty infiltration,[28,29] and body composition analysis has revealed reduction of muscle mass in the arms and legs.[27,29] Weakness can be assessed by enquiring if patients experience difficulty or weakness in climbing stairs, or in getting up from a chair or bed without using their hands. Formal muscle strength testing is useful. Assessment of the strength of the hip flexors is done by asking the patient to get out of a chair or get up after crouching without using his/her arms. Maximal duration of leg extension while seated and handgrip tests are also quantifiable tests of proximal muscle strength.

Osteopenia and osteoporosis are common, owing to the direct effects of cortisol excess on the replication and differentiation of osteoblasts resulting in uncoupling of bone turnover, as well as indirect effects on intestinal and renal calcium homoeostasis, impairment of pituitary hormone secretion, and catabolic effects on muscles.[29,30] A history of fractures, typically of the feet, ribs, or vertebrae after minimal or no trauma, is frequent, especially in men, suggesting that cortisol-induced hypogonadism plays an associated role in the pathogenesis of bone fragility. A number of studies have shown decreased bone mineral density (BMD) in Cushing disease.[29,30] However, BMD underestimates the impact of chronic hypercortisolism that also alters the bone microarchitecture.[31] Consequently, fractures contrasting with normal or minimally altered BMD are common in glucocorticoid-induced osteoporosis.[30,31] Avascular necrosis of bone, a rare complication of endogenous hypercortisolism, is more common in iatrogenic hypercortisolism.

Hirsutism, as well as pustular acne, reflecting increased secretion of androgens, or papular acne, reflecting pure glucocorticoid excess, are common in both women and men.

Most patients experience emotional and cognitive changes including increased fatigue, irritability, depressed mood, decreased libido, insomnia, anxiety, impaired memory and concentration, and changes in appetite and sleep.[32,33] Psychiatric symptoms may be exacerbated in vulnerable individuals.[34] Irritability and sleep disturbances with early falling asleep because of fatigue followed by persistent and early night awakening are often the earliest symptoms. According to current classifications of mental health disorders, between 52% to more than 80% of patients meet the criteria for a major affective disorder.[33] The depressed mood may induce suicide.[34] The time course of psychiatric symptoms is characteristically intermittent, with alternation of depressed phases with periods of excessive arousal, in contrast to the constant dysphoria reported by depressed patients without Cushing syndrome. A minority of patients are manic.[34] Psychiatric symptoms are often refractory to common medical therapies, including antidepressants, but rapidly improve following cessation of hypercortisolism. During intense hypercortisolism, some patients may develop acute steroid psychosis that associates agitation and paranoid symptoms and can prevent adherence to oral therapy and render parenteral administration of steroidogenic inhibitors necessary.[35] Cognitive function is also frequently negatively affected, with impaired memory and impaired concentration being the most frequent symptoms.[33,36] Imaging studies have revealed morphological and functional changes in the whole brain and in cerebral areas that are rich in glucocorticoid receptors, particularly the hippocampus, amygdala, and prefrontal cortex, which are fundamental regions associated with emotional and cognitive functions such as memory.[37]

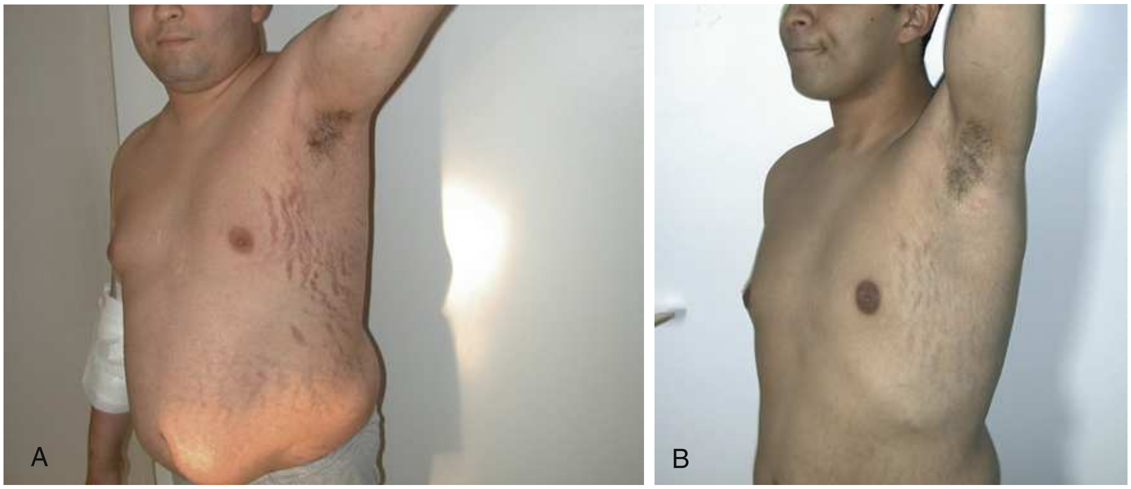

Fig. 7.5 Purple striae before and 3 months after successful pituitary surgery in an 18-year-old man. **A,** Before surgery: typical large violaceous striae. **B,** After surgical remission. Disappearance of the purple appearance of the stretch marks. Also note the weight loss and thinning of the face compared to the preoperative habitus.

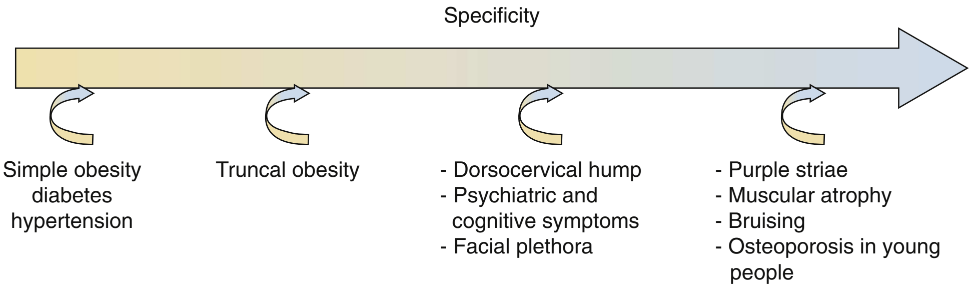

Specificity
Simple obesity diabetes hypertension
Truncal obesity
- Dorsocervical hump
- Psychiatric and cognitive symptoms
- Facial plethora
- Purple striae
- Muscular atrophy
- Bruising
- Osteoporosis in young people

Fig. 7.6 Classification of symptoms of Cushing syndrome in increasing order of specificity.

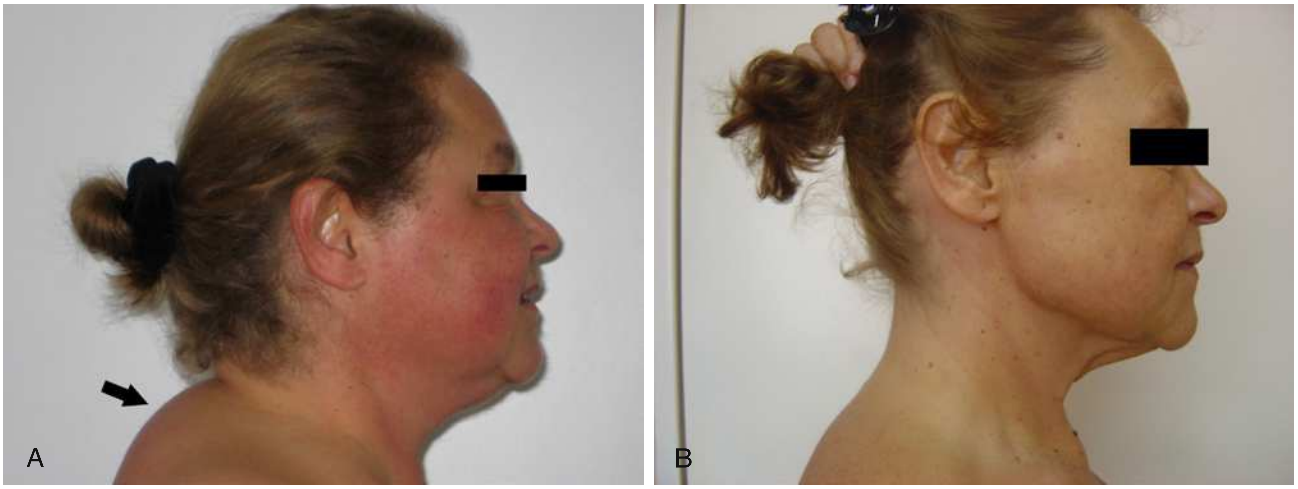

Fig. 7.7 Favorable evolution of buffalo hump, facial rounding, and plethora following successful pituitary surgery in a 60-year-old woman. **A,** Before surgery. **B,** One year after surgical remission. Note the disappearance of the buffalo hump (*arrow*) and the facial plethora.

Hypertension is frequent (Table 7.1),[29,33] and although hypertension is common in the general population, its presence in patients younger than 40 years of age, especially if it is difficult to control, may alert physicians to the syndrome.[2,38] Fungal infections of the skin, such as mucocutaneous candidiasis and pityriasis versicolor, staphylococcus infection of the face after shaving with a razor in men, and increased latency of healing of small everyday skin wounds, are common features. Poor wound healing and wound dehiscence occur less often but are an important consideration in patients with severe Cushing syndrome who are treated surgically.

All of these clinical features are exacerbated in patients with intense hypercortisolism (see Cushing Disease as an Emergency Condition).

Decreased libido associated with erectile dysfunction is common in men. Women usually experience menstrual irregularity, oligomenorrhea, and infertility, reflecting polycystic ovary syndrome when the intensity of hypercortisolism is moderate, or secondary amenorrhea resulting from hypogonadotroph hypogonadism in severe Cushing syndrome.[29]

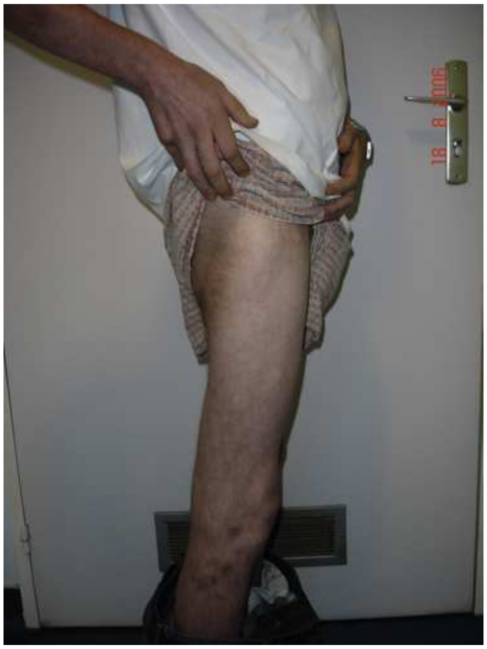

Fig. 7.8 Profound proximal amyotrophia of the thighs of a 23-year-old man with Cushing disease. Note the ecchymosis on the lateral face of the knee and leg.

Nonspecific Biochemical and Radiological Investigations

Hypokalemic metabolic alkalosis is usually observed when hypercortisolism is intense and is therefore more frequent in ectopic ACTH syndrome than in Cushing disease. It is mainly secondary to activation of the mineralocorticoid receptor by cortisol excess at the renal tubule, because of saturation of the enzyme 11β-hydroxysteroid dehydrogenase type 2, which inactivates cortisol to cortisone.[35] Serum albumin inversely correlates with cortisol levels, but this is clinically significant only at very high cortisol levels.[39] Drastic reductions in serum albumin should alert the physician to the possibility of concomitant pathology, such as infection.

Chronic hypercortisolism increases clotting factors, including factor VIII, fibrinogen, and von Willebrand factor, and reduces fibrinolytic activity, resulting in a 4-fold to 10-fold increased risk of thrombotic events.[40-42] Deep vein thrombosis and pulmonary thromboembolism may be more frequent after pituitary surgery for Cushing disease,[41] and retrospective studies suggest a beneficial effect of thromboprophylaxis.[41,42]

Cortisol regulates both lipolytic and adipogenic processes in a complex fashion.[27] Lipid abnormalities include increases in very low-density lipoproteins, low-density lipoproteins, and triglycerides, and usually a decrease in high-density lipoproteins.[33]

Cushing syndrome is characterized by insulin resistance and hyperinsulinemia, with glucose intolerance and diabetes mellitus occurring in 30% to 70% of patients.[27,29,33] In patients with Cushing syndrome (as with other etiologies of secondary diabetes), diabetes mellitus is more accurately diagnosed using an oral glucose tolerance test than fasting blood glucose. The potentiation of multiple cardiovascular risk factors in Cushing syndrome, such as hypertension, insulin resistance and glucose intolerance/diabetes mellitus, dyslipidemia, and hypercoagulability, is responsible for accelerated vascular disease, including cerebrovascular accidents and myocardial infarction.[29,33,43-45] A direct pathogenic effect of cortisol on blood vessels and the myocardium is also suspected.[46] Biomarkers for cardiovascular disorders include increased carotid artery intima-media thickness and atherosclerotic plaques seen on Doppler ultrasonography[47] or computed tomography (CT) coronary angiography.[48] On echocardiography, Cushing syndrome is characterized by left ventricular hypertrophy and diastolic and systolic dysfunction that may be partially explained by increased myocardial fibrosis.[29] Magnetic resonance imaging (MRI) studies have found left ventricle hypertrophy associated with decreased systolic strain and impaired diastolic filling caused by an abnormal relaxation pattern in patients with Cushing syndrome.[49]

Hypercortisolism suppresses the thyroidal, gonadal, and growth hormone (GH) axes. Low triiodothyronine levels attributed to the inhibition of thyroxine deiodination is common. Thyroid-stimulating hormone (TSH) release is also decreased with a loss of its nocturnal surge, resulting in reduced thyroxine and triiodothyronine levels, with reduced TSH levels being correlated with the intensity of hypercortisolism.[50] In both men and women, low levels of luteinizing hormone, follicle-stimulating hormone, and gonadal steroids, consistent with hypogonadotropic hypogonadism, are common in intense hypercortisolism, whereas polycystic ovary syndrome is common in patients with Cushing disease of moderate intensity.[29,33] Hypercortisolemia reduces GH secretion during sleep and blunts the GH response to stimulation tests.[29,51]

Clinical Spectrum of Cushing Disease. Who Should Be Tested for Cushing Syndrome?

KEY POINTS

- Generalized biochemical screening for CD in obese, diabetic and hypertensive patients is not recommended. Clinical suspicion leading to biochemical screening is based on clinical examination for "specific" symptoms of Cushing's syndrome, occurrence of unexplained changes in cognition and mood, and features unusual for the condition of the patient.

The typical patient with Cushing disease is a middle-aged woman who complains of the gradual development of symptoms over several years. However, the clinical presentation of patients with Cushing disease encompasses a wide spectrum and varies with regard to the type, number, and severity of symptoms, which are in turn to some degree related to the intensity and duration of hypercortisolism, patient sex and age (with more severe forms in older patients and male patients),[52] individual sensitivity to glucocorticoids,[53,54] and preexisting sporadic or inherited vulnerabilities such as overweight, hypertension, and diabetes.[55] The clinical presentation of pituitary corticotroph macroadenomas, apart from visual field changes caused by suprasellar expansion, is not unique. In contrast, rare and extremely aggressive corticotroph macroadenomas present at a slightly younger age, and cavernous sinus and dural involvement may result in cranial neuropathies and facial neuralgia. Only a few case reports attest to overt malignancy, with cerebrospinal or extracranial metastasis of ACTH-producing pituitary tumors, but the relative prevalence of corticotropinomas is significant among aggressive and malignant pituitary tumors.[7-9]

As early as 1964, several attempts have been made to develop a diagnostic score that can detect an increased probability of a patient having Cushing syndrome before performing biochemical assays.[25,26] Although none of these attempts achieved any great accuracy, these studies highlight that "catabolic" symptoms such as osteoporosis, muscle atrophy, purple striae, and easy bruising are among the more specific symptoms and are associated with the highest likelihood ratio of Cushing syndrome (Fig 7.6). However, these clinical symptoms are absent in a number of patients with Cushing syndrome. In addition, diagnosing Cushing disease at an early stage is an important challenge, given the deleterious impact of prolonged exposure to excess cortisol. This raises the issue of screening for the disease in poorly symptomatic patients and/or patients lacking specific symptoms, such as diabetic and obese patients. This issue is important given the increased prevalence of these diseases and the fact that Cushing syndrome is a treatable cause of secondary obesity and diabetes. Systematic screening studies using biochemical investigations in unselected patients with type 2 diabetes mellitus referred to specialized centers found a prevalence of Cushing syndrome ranging from 0% to 3.3%.[56] In the largest multicenter study performed to date, involving more than 800 outpatients with diabetes in Italy, the prevalence was 0.6%.[57] Contrary to patients with a clinical suspicion of Cushing syndrome, adrenal adenomas with autonomous cortisol secretion responsible for mild cortisol excess, including normal urinary free cortisol (UFC), were much more prevalent than were cases of Cushing disease.[56] Furthermore, the impact of treatment of mild Cushing syndrome on glycemic control was not mentioned in the majority of cases. The prevalence of Cushing syndrome in obesity has been assessed in a metaanalysis involving 5819 patients.[58] Among obese patients with nonspecific symptoms, including type 2 diabetes, the prevalence of Cushing syndrome ranged between 0% and 1.1%.[58] Studies conducted in patients with hypertension suffer from major methodological drawbacks that prevent accurate evaluation. Rare screening studies in osteoporotic patients have found a prevalence ranging from 1.3% to 3.8% in unselected patients, corresponding in almost all cases to adrenal adenomas associated with mild Cushing syndrome.[56]

A screening strategy is justified is it is supported by epidemiological concerns and sufficient evidence that its efficacy benefit will outweigh its drawbacks.[56] The biological spectrum of “occult” Cushing syndrome and its relatively low prevalence may negatively affect the performance of biochemical diagnostic tests, favoring the occurrence of false positives.[56] Furthermore, whether curing minimal hypercortisolism favorably affects clinical outcomes remains unknown. Last, the feasibility of large-scale screening, in terms of workload and costs, is highly questionable, given the high prevalence of patients with conditions to screen. As recommended by the Endocrine Society, widespread screening appears not to be indicated, and, before considering biochemical tests, it is mandatory to have clinical suspicion based on factors that increase the pretest probability of Cushing syndrome.[59] This includes careful clinical examination to look for specific symptoms of Cushing syndrome, to enquire if symptoms have accumulated and worsened over time, to ascertain the occurrence of unexplained changes in cognition, short-term memory, insomnia and mood, and to look for features that are unusual for the patient’s condition, such as osteoporosis and hypertension in a young person, thin skin in men, and so on.[59]

BIOCHEMICAL DIAGNOSIS OF CUSHING SYNDROME

KEY POINTS

- The choice between first-line biochemical investigations for the diagnosis of Cushing’s syndrome should be based primarily on the patient’s conditions, e.g. individual characteristics that can lead to false positive or negative results of tests.

General Considerations

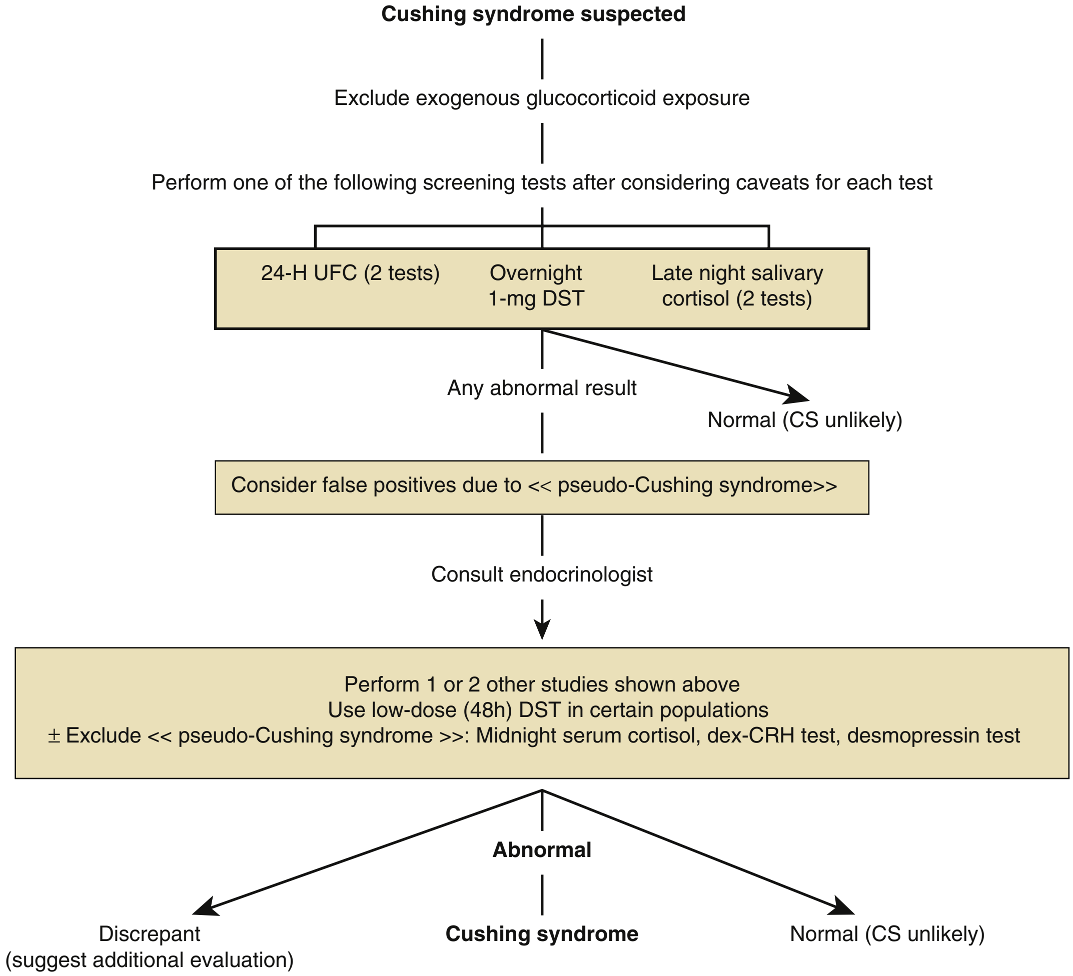
First-line biochemical tests used for the diagnosis of Cushing syndrome are aimed at establishing the cardinal biochemical features of Cushing syndrome, these being excessive production of cortisol, loss of the normal circadian rhythm of cortisol secretion, and impaired feedback of the hypothalamic-pituitary-adrenal (HPA) axis. As mentioned previously, it is important to test patients with a significant pretest probability of Cushing syndrome (see Clinical Aspects) to ensure the best performance of biochemical tools[56,59,60] and to use a first-line test with high sensitivity to avoid missing milder cases.[59] All tests have limitations related to the individual patient situation (Table 7.2) that should guide the choice of the test. All tests have imperfect sensitivity and specificity.[60,61] Imperfect sensitivity implies the need for repeated evaluation if the patient presents with convincing clinical features. Imperfect specificity implies that any abnormal test should be confirmed by a second first-line test to confirm the diagnosis (Fig. 7.9).[59] This strategy increases confidence in the test results when consistently normal or abnormal results are obtained. Second-line tests should be performed in expert centers in ambiguous cases.

As with all hormone assays, physicians must be aware that results for a single sample measured in different assays may differ.[62] Caution should be exerted when considering results near the cutoff value on a single measurement, as subnormal or slightly increased results can often be explained by assay variability. It also important to consider that no “universal” threshold for any biochemical measurement exists, and that normal ranges vary substantially depending on the method used, implying the need to interpret test results in the context of an appropriate and accurately defined normal range. Additionally, the performance of tests in real-life practice is often worse than that quoted in the literature.[63]. This may be because of the greater expertise of laboratories in tertiary expert centers but also attributed to the retrospective design of studies and the use of healthy subjects in the control group, which results in decreases in both the specificity and the positive likelihood ratio.[60,61] Lastly, it is important to keep in mind that any intercurrent illness will appropriately stimulate HPA axis function and result in increased cortisol secretion, emphasizing the importance of testing patients in stable clinical conditions.

TABLE 7.2 **Main Causes of False Results in Biochemical Tests Used for the Diagnosis of Cushing Syndrome**

Screening test	False positive	False negative
Urine free cortisol	Polyuria Medications Overcollection Crossreactivity/immunoassays Nonneoplastic hypercortisolism/stress	Undercollection Moderate to severe renal insufficiency
Low-dose dexamethasone suppression test	Increased CBG (pregnancy, chronic active hepatitis, oral estrogens) Multiple medications Rapid metabolism of dexamethasone Impaired absorption of dexamethasone Nonneoplastic hypercortisolism/stress	Decreased CBG (liver cirrhosis, nephrotic syndrome) Slow metabolism of dexamethasone
Late-night salivary cortisol	Age, hypertension, diabetes/dependent on the assay Shift workers Tooth bleeding Nonneoplastic hypercortisolism/stress	Improper collection

CBG, Corticosteroid-binding globulin.
(Data from references 3,29,33,34,235.)



Cushing syndrome suspected
Exclude exogenous glucocorticoid exposure
Perform one of the following screening tests after considering caveats for each test
24-H UFC (2 tests)
Overnight 1-mg DST
Late night salivary cortisol (2 tests)
Any abnormal result
Normal (CS unlikely)
Consider false positives due to << pseudo-Cushing syndrome>>
Consult endocrinologist
Perform 1 or 2 other studies shown above
Use low-dose (48h) DST in certain populations
± Exclude << pseudo-Cushing syndrome >>: Midnight serum cortisol, dex-CRH test, desmopressin test
Abnormal
Discrepant (suggest additional evaluation)
Cushing syndrome
Normal (CS unlikely)

Fig. 7.9 Algorithm for testing patients suspected of having Cushing syndrome, modified from Endocrine Society recommendations. *CRH,* Corticotropin-releasing hormone; *CS*, Cushing syndrome, *DST*, dexamethasone suppression test; *UFC,* urinary free cortisol. The diagnosis of Cushing syndrome: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab.* 2008;93:1526-1540.)

First-Line Biochemical Investigations

Urinary Free Cortisol. Under normal conditions, 5% to 10% of plasma cortisol is free or unbound and physiologically active. The kidneys filter unbound cortisol, with most being reabsorbed, while the remainder is excreted unmodified. A 24-hour UFC collection produces an integrated measure of circulating serum cortisol during the day. The major drawback of the test is the potential for overcollection or undercollection of the 24-hour specimen. Consequently, written instructions must be given to the patient, and creatinine excretion in the collected urine should be measured to assess completeness (~1 g/24 hours in a 70-kg patient with normal kidney function). Creatinine measurement cannot be used to correct for incomplete collection, as rates of cortisol and creatinine excretion are not parallel over the 24-hour period. Various groups have attempted to overcome collection issues by proposing shorter collection periods focusing on periods when the loss of circadian rhythm differs most from normal controls, such as at night (from 8:00 PM to 8:00 AM), but this approach has not been widely accepted.[64,65] High-performance liquid chromatography and tandem mass spectrometry (LC-MS/MS) is now commonly used to measure UFC, which overcomes the problem of crossreactivity of other endogenous or exogenous glucocorticoids that occurs in some, but not all, immunoassays. Consequently, UFC values are invariably lower when measured by LC-MS/MS as compared with immunoassays because of the lack of crossreactivity with interfering glucocorticoid metabolites.[66] However, aside from the rare situation of spurious results owing to exogenous steroid intake, direct head-to-head comparison studies show that the diagnostic performance of mass spectrometry and selected immunoassays is comparable,[66] assuming that correctly established assay-specific normal ranges are used.

A number of conditions influence urinary cortisol excretion (Table 7.2). Diuresis stimulates cortisol excretion, and mildly increased UFC is observed in patients with polydipsia.[67] Of more clinical relevance, UFC is significantly decreased with moderate and severe renal insufficiency and so should not be used in this situation.[68] Although values greater than 4-fold of normal are pathognomonic of Cushing syndrome, a recent metaanalysis and several studies show that the sensitivity of UFC for the diagnosis of Cushing syndrome is 92% to 96% and is lower than that of late-night salivary cortisol (LNSC) or the 1-mg dexamethasone suppression test (DST).[61] False negatives are more likely to occur in patients with Cushing syndrome of mild intensity.[69-72] Furthermore, it should be stressed that UFC is highly variable from one day to another and, in a series of 162 patients with overt Cushing disease, 5% had at least one out of four UFC collections within the normal range, emphasizing the need for multiple collections.[73] Consequently, it may be more pertinent to use UFC as a confirmatory test rather than a screening test.[61]

TABLE 7.3 Examples of Drugs That May Interfere With Dexamethasone Suppression Tests

Drugs that accelerate dexamethasone metabolism by induction of CYP3A4	Drugs that impair dexamethasone metabolism by inhibition of CYP3A4	Drugs that increase CBG and may falsely elevate total serum cortisol results
• Carbamazepine	• Aprepitant, fosaprepitant	• Estrogens
• Ethosuximide	• Cimetidine	• Mitotane
• Phenobarbital	• Diltiazem, verapamil, amiodarone	
• Phenytoin	• Fluoxetine	
• Pioglitazone	• Ketoconazole, Itraconazole, fluconazole, etc.	
• Pyrimidone	• Macrolides (erythromycin, clarithromycin, etc.)	
• Rifampin	• Ritonavir	
• Rifapentine		
False positive possible	False negative possible	False positive possible

CBG, Corticosteroid-binding globulin; *CYP*, cytochrome P450.

Late-Night Salivary Cortisol. The rationale for the measurement of LNSC is 2-fold. Firstly, salivary cortisol is a reflection of plasma free cortisol concentration, almost circumventing the changes in total cortisol that are caused by corticosteroid-binding globulin (CBG) alterations, and more specifically the increase in cortisol in women taking estrogens.[74] Secondly, saliva can be sampled at the critical period during which plasma cortisol reaches its nadir.[72] From a practical perspective, LNSC offers the advantage of nontraumatic sampling that can be performed conveniently in both in- and outpatient settings.[75] LNSC is also convenient in children and obese patients, where venipuncture may be difficult. Salivary cortisol is stable for several days at room temperature, for weeks at 4° C, and can be sent to the testing laboratory by mail. Self-sampling can be easily repeated when cyclical Cushing syndrome is suspected.[65] Studies suggest that there is no difference in the diagnostic performance if sampling is performed earlier than 11:00 PM, whereas another study suggested that patients could sample saliva at their normal bedtime.[74,76] The main drawbacks are the possible contamination of samples by blood, meaning teeth should not be brushed just before sampling, night-shift work, which can induce different patterns of the circadian rhythm of cortisol in a subset of individuals (termed “shifters”),[77] and patients having recently changed their “time-zone.” LNSC measurement is performed using immunoassay, providing wide variations in cutoffs depending on the assay used, or by LC-MS/MS. The latter provides the possibility of measuring both cortisol and cortisone. Saliva contains higher levels of cortisone than cortisol owing to conversion by the 11β-hydroxysteroid dehydrogenase (11β-HSD) type 2 enzyme in the salivary glands, which “amplifies” the cortisol signal. The relative performance of immunoassays versus LC-MS/MS and whether specific measurement of salivary cortisone is an important additional diagnostic parameter have been a matter of debate.[63,74] Normal values increase with age and the presence of diabetes and hypertension,[74] therefore requiring validation of normal ranges based on the population being studied to ensure the best performance, especially in the context of mild hypercortisolism.

Two saliva samples are recommended to ensure the best diagnostic performance,[59,63] with sensitivity and specificity ranging from 94% to 97% and 91% to 95%, respectively, in a recent metaanalysis.[61] Several publications suggest that LNSC is more suitable for diagnosing mild forms of Cushing disease with a normal UFC.[69-72,78]

Overnight Dexamethasone Test. The rationale of the test is that, in normal individuals, administration of the synthetic glucocorticoid dexamethasone results in suppression of the HPA axis, whereas patients with Cushing syndrome are resistant, at least partially, to this negative feedback. The overnight DST correspond to 9:00 AM serum cortisol measurement after a single dose of 1 mg of dexamethasone administered at 11:00 PM. Its low cost and simplicity, as well as its performance, explain its widespread use.[59,61] The dose of dexamethasone used and that performance of the test are similar in obese and nonobese subjects.[79] The measurement of salivary rather than serum cortisol has been proposed to circumvent the issue of variations in CBG and increased total cortisol in women taking estrogens.[59,74,80] In the context of screening, a relatively “low” threshold of 50 nmol/L has been adopted to ensure the best sensitivity,[81,82] which is as high as 95%.[59-61] The major drawback of the test is a roughly 10% rate of false positives,[57,82] resulting in a specificity of around 90%.[61] The interpretation of these values, in practical terms, is that impaired suppression does not necessarily mean that a patient has Cushing syndrome. Conversely, adequate suppression is very strong evidence against the diagnosis. Factors such as variable absorption and increased or decreased dexamethasone metabolism by CYP3A4 owing to other compounds[59] (Table 7.2 and 7.3) may be responsible for a number of false results. Therefore, a history of symptoms of malabsorption or bariatric bypass surgery should be noted, and a careful drug history (see http://medicine.iupui.edu/flockhart/table.htm) should be taken before the test is used in a patient.[83] Measurement of plasma dexamethasone has been proposed in patients with conditions that may induce or inhibit CYP3A4 activity. However, this useful adjunct is not widely used because of the added cost and some uncertainty of the threshold to employ.[80] One solution to overcome malabsorption is to use one of the published intravenous DSTs, recognizing that criteria for response in this case have not been standardized.[59] Pregnancy and other causes of increased or decreased CBG (such as exogenous estrogens, chronic hepatitis, and nephrotic syndrome) should also be excluded, because these are likely to result in false-positive and false-negative tests.[62,84] Combined oral contraceptive pill or hormone replacement therapy containing estradiol should be stopped for 4 to 6 weeks before performing tests.[84] If stopping exogenous estrogens is not possible, or if the patient is pregnant, UFC or salivary cortisol should be used, as these tests reflect the free cortisol level.

Second-Line Biochemical Investigations

Low-Dose Dexamethasone Suppression Test. Dexamethasone is given in doses of 0.5 mg for 48 hours, at 6-hourly intervals, beginning at 9:00 AM on day 1, and serum cortisol is obtained at 9:00 AM on day 3. In a recent metaanalysis, both the 2-day and the 1-mg overnight DST analyzed with a postdexamethasone serum cortisol cutoff of 1.8 μg/dL (50 nmol/L) appeared to have approximately comparable performance.[61] No head–to-head comparison of the two tests has been conducted, but a few studies suggest that the low-dose DST (LDDST) is less susceptible to interference owing to dexamethasone malabsorption and stress activation of the HPA axis[57,82,85,86] than the overnight

1-mg test. Given its cumbersome protocol, the LDDST is usually considered as a second- or third-line test for patients with equivocal results. Measurement of salivary cortisol can be a substitute for serum cortisol in women taking the combined oral contraceptive pill.

Midnight Serum Cortisol. Similarly to LNSC, the purpose of midnight serum cortisol (MSC) measurement is to demonstrate elevated concentrations in the period when physiological concentrations reach their nadir. MSC concentration has a roughly similar diagnostic performance to LNSC.[61,71] However, there has been some controversy with regard to the appropriate cortisol threshold to use. A concentration of 50 nmol/L, which was determined in unstressed healthy medical students, effectively excludes Cushing syndrome but results in a false-positive rate of approximately 25%.[59] Therefore, the suggested cutoff criteria are higher, at 7.5 to 8.3 μg/dL (207–229 nmol/L).[82,87,88] Of note, MSC increases in women taking estrogens. The main caveat of this approach is the need to sample blood at midnight, which cannot usually be done in an outpatient setting.

Other Biochemical Investigations

The desmopressin test and dexamethasone-CRH test may be used to differentiate Cushing disease from functional activation of the HPA axis ("pseudo-Cushing") in patients with mild hypercortisolemia (see Differential Diagnosis of Adrenocorticotropic Hormone–Dependent Cushing Syndrome).

Cortisol is incorporated into the hair cells by diffusion from blood capillaries, and as hair has a growth rate of approximately 1 cm/month, it is a suitable matrix for the estimation of mid- to long-term tissular exposure to circulating cortisol. Similar to saliva, 11β-HSD type 2 enzyme in sweat glands of the skin generates cortisone from cortisol in hair. Several studies have reported a similar diagnostic accuracy of cortisol and cortisol plus cortisone measurement in a single hair sample to that of UFC in patients with overt Cushing syndrome.[89,90] Owing to its ability to reflect long-term glucocorticoid exposure, hair cortisol measurement may be particularly useful for diagnosing intermittent/cyclical Cushing syndrome.[89,90] Although hair sampling has a number of practical advantages (noninvasive procedure not requiring specific timing, ability to store hair samples at room temperature and send them by mail to the testing laboratory), it also suffers from several limitations, such as the cumbersome and time-consuming preparation and extraction of hair samples. It may therefore be best reserved for difficult cases.

ESTABLISHING ADRENOCORTICOTROPIC HORMONE–DEPENDENCY OF CUSHING SYNDROME

The strategy for the differential diagnosis of Cushing syndrome begins with measurement of plasma ACTH to distinguish between ACTH-dependent and ACTH-independent causes (Fig. 7.10). In Cushing disease, tumoral corticotrophs show reduced sensitivity to the negative feedback normally exerted by cortisol. Hence, ACTH concentrations are inappropriate, for example, neither low nor undetectable as they are in Cushing syndrome owing to a secreting adrenal tumor. Preanalytical steps (sampling into ethylenediaminetetraacetic acid tubes kept in an ice water bath, rapid centrifugation, aliquoting, and, if necessary, freezing within 1 hour) are critical to avoid ACTH degradation by peptidases and falsely decreased concentrations. Using sensitive two-site immunoradiometric assays, ACTH concentrations less than 10 ng/L in a context of hypercortisolism confirm the ACTH independence of the syndrome, whereas ACTH concentrations greater than 20 ng/L diagnose ACTH dependence. Repeated measurements of cortisol and ACTH in blood samples drawn simultaneously are necessary, because 3% to 4% of patients with Cushing disease have been shown to occasionally have suppressed ACTH levels.[91] When the basal ACTH level is indeterminate (10–20 ng/L [2–4 pmol/L]), a situation that was described in 9% of patients with Cushing disease,[91] a CRH test should be performed. Patients with primary adrenal disease rarely show maximal ACTH values greater than 20 to 30 ng/L (4–6 pmol/L), although patients with Cushing disease usually exceed this value.

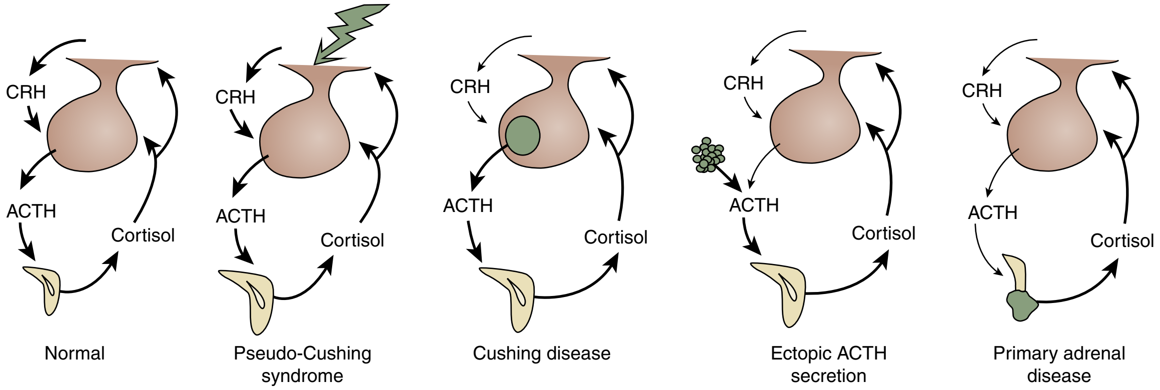


Fig. 7.10 Pathophysiology of the hypothalamic-pituitary-adrenal axis in hypercortisolemic states. Corticotropin-releasing hormone (CRH) secretion from the hypothalamus normally stimulates adrenocorticotropic hormone (ACTH) secretion from the pituitary gland. This in turn results in increased cortisol production from the adrenal glands. The system is modulated by negative feedback inhibition of both CRH and ACTH secretion by cortisol. In pseudo-Cushing syndrome, the CRH neuron is activated by central input (*large shaded arrow*), resulting in increased CRH output that results in hypercortisolism. Increased cortisol production restrains corticotroph activation but does not completely reverse the activation of the CRH neuron, so that mild to moderate hypercortisolism may persist. In Cushing disease, a corticotroph adenoma secretes ACTH in excess and is inhibited only partially by rising cortisol levels. In this setting and that of ectopic ACTH secretion and primary adrenal disease, the CRH neuron is suppressed by hypercortisolism. In the case of ectopic ACTH secretion, excessive secretion of ACTH from a nonpituitary tumor is typically not inhibited by glucocorticoid feedback. In this setting and that of autonomous production of cortisol by the adrenal gland, ACTH secretion by normal corticotrophs is suppressed by hypercortisolism.

TABLE 7.4 Conditions Associated With Chronic Nonneoplastic Functional Hypercortisolism

Conditions associated with chronic nonneoplastic functional hypercortisolism
Intense chronic physical exercise
Anorexia nervosa
Pregnancy
Sleep apnea
Anorexia nervosa
Glucocorticoid resistance syndrome
Uncontrolled diabetes
Alcoholism, especially withdrawal
Psychiatric disorders/severe depression

(Modified from and reproduced with permission from Nieman LK, Biller BMK, Findling JW, et al. The diagnosis of Cushing syndrome: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab*. 2008;93:1526-1540.)

In all cases, caution is important in interpreting plasma ACTH results because of marked variability in the results between assays and possible suboptimal assay performance in routine conditions.[92,93] Indeed, a significant number of patients with ACTH-independent Cushing syndrome may exhibit nonsuppressed plasma ACTH concentrations.[93] Use of the CRH test and measurement of plasma ACTH with an additional assay may be important in discordant cases.[91,92] In the same vein, caution is also important in the analysis of abdominal CT scans if these are performed in ambiguous cases, given the 20% prevalence of adrenal macronodules, which may be unilateral and mimic adrenal disease in longstanding Cushing disease.[94]

DIFFERENTIAL DIAGNOSIS OF ADRENOCORTICOTROPIC HORMONE–DEPENDENT CUSHING SYNDROME

The differential diagnosis of ACTH-dependent Cushing syndrome involves two stages: in the presence of moderate hypercortisolism with no specific Cushingoïd symptoms, to rule out causes of functional hypercortisolism; in the presence of overt hypercortisolism with florid Cushing syndrome, to rule out an ectopic ACTH syndrome

KEY POINTS

- Once the diagnosis has been made, the first step in the etiological workup to identify the cause of Cushing's syndrome is the concomitant measurement of serum cortisol and plasma ACTH.
- Functional (e.g. non-neoplastic) causes of Cushing's syndrome such as "pseudo-Cushing's syndrome" and, more rarely, inactivating mutations in the NR3C gene encoding the glucocorticoid receptor, should be excluded in the presence of mild ACTH-dependent hypercortisolism with few or no specific Cushingoïd symptoms.
- CD accounts for approximately 90% of ACTH-dependent cases. This likelihood is increased in an individual with progression of symptoms over a few months, hypokalemia, and large increases in urinary free cortisol, serum cortisol, and plasma ACTH.
- Pituitary MRI is a cornerstone of investigations in ACTH-dependent Cushing's syndrome given the frequency of CD. However, it may be negative in at least a third of patients with CD.
- Although it is not free from false positives and false negatives, BIPSS, performed by an experienced team, is the reference tool for the diagnosis of CD when pituitary imaging is negative. The timing of the BIPSS during the etiological assessment is variable between expert teams.

Hypercortisolemic States Without Cushing Syndrome

Nonneoplastic Hypercortisolism ("Pseudo-Cushing Syndrome"). Activation of the HPA axis is a common adaptive response to situations where homeostasis is challenged. A number of clinical situations and pathologies may cause chronic stimulation of the HPA axis through neural pathways and result in a state of (usually mild) ACTH-dependent hypercortisolism that disappears after resolution of the underlying condition (Fig. 7.10 and Table 7.4). The case of "nonneoplastic hypercortisolism" is not a diagnostic issue when it occurs during situations that are clinically very distinct from Cushing syndrome, such as undernutrition (including anorexia nervosa) or intense athletic activity. Conversely, it can represent a true diagnostic challenge, also termed "pseudo-Cushing syndrome," where patients with nonneoplastic hypercortisolism display nonspecific clinical features of Cushing syndrome, such as visceral obesity, hypertension, hyperglycemia, menstrual disorders, and osteoporosis. This may be the case in patients with chronic alcoholism, psychiatric conditions, polycystic ovary syndrome, and diabetes mellitus with poor glycemic control.[95,96]

As for the etiological diagnosis of Cushing disease, differential diagnosis should be conducted using a progressive probabilistic approach. This should start with a thorough history and physical examination. Patients with depressive illness responsible for pseudo-Cushing syndrome usually have major forms of permanent depression, especially psychotic depression,[95] that do not resemble the most common pleiomorphic and fluctuating psychiatric symptoms seen in Cushing syndrome.[34] Collaboration with expert psychiatrists may be useful for defining the psychiatric picture. Patients with pseudo-Cushing syndrome rarely have specific clinical manifestations. Although their presence strongly argues for true Cushing syndrome, their absence does not exclude mild forms of Cushing disease.[85] In addition, facial fullness with plethora, purple striae, and proximal myopathy may be present in alcoholic patients. The intensity of biochemical abnormalities should also be considered. The 24-hour UFC value is often moderately increased, and elevations of UFC three to four times the upper limit of normal are highly suggestive of Cushing syndrome.[95,96] Chronic stressors are often responsible for false positives of the overnight 1-mg DST associated with the 50-nmol/L cortisol threshold. Several studies suggest that the LDDST may be more specific in identifying pseudo-Cushing syndrome among those not suppressed according to the 1-mg test.[82,85,86] LNSC and MSC determinations are probably the best discriminating biochemical tools because pseudo-Cushing syndrome is characterized by preservation of the circadian rhythm of cortisol secretion, albeit at higher absolute levels.[85,87,95] Increased LNSC has been found in some patients with poorly-controlled diabetes mellitus and hypertension, requiring revised thresholds.[74] It should also be remembered that acute alcohol withdrawal occurring during hospitalization is a major stressor in patients suffering from chronic alcoholism. Second-line investigations in ambiguous cases include the desmopressin test and the dexamethasone-CRH test. The desmopressin test takes advantage of the overexpression of the aberrant expression of its cognate receptor, the vasopressin V2 renal receptor, in approximately 85% of corticotroph adenomas contrary to noncancerous corticotrophs.[97,98] An increase in plasma ACTH of less than 6 pmol/L (>27 ng/L) during the test has been associated with 75% and 87% sensitivities and 90% specificity.[95,96] There is therefore some overlap between the two groups, but the higher the ACTH response the more likely it is to be Cushing disease. The rationale of the dexamethasone-CRH test relies on the different degree of sensitivity to glucocorticoid feedback between patients with pseudo-Cushing syndrome and patients with Cushing disease. In the latter, low doses of dexamethasone are insufficient to inhibit the cortisol increase in response to CRH, whereas patients with pseudo-Cushing syndrome are expected to be unresponsive to CRH while being suppressed by dexamethasone.[95,96] Typically, 2 mg of dexamethasone is given orally as eight doses over 2 days before performing the CRH test. Various thresholds for cortisol responses have been proposed, but the test is far from being completely specific.[95,96] It does not perform better than the dexamethasone part of the protocol, according to some studies,[85,86] and, in comparative studies, has lower accuracy than both the desmopressin test[82] and MSC.[85] Of note, psychiatrists have used the LDDST and the dexamethasone-CRH test to characterize and classify neuropsychiatric disorders,[95] casting doubt on the diagnostic value of the tests in depression-induced activation of the HPA axis.

In ambiguous cases, biochemical reevaluation is needed to make a diagnosis, especially after treatment of the putative causal condition (glycemic control in diabetic patients, treatment of depression, recovery from alcoholism). Although an obvious pituitary adenoma on MRI may be diagnostic, we caution against the use of medical imaging because of the high prevalence of small artefactual pituitary images.[99] Similarly, bilateral inferior petrosal sinus sampling (BIPSS) is discouraged because it cannot distinguish neoplastic from nonneoplastic hypercortisolism, both conditions being pituitary ACTH–driven and associated with high central-to-peripheral ACTH gradients.[95]

NR3C1 Mutations and General Resistance to Glucocorticoids.

Glucocorticoid resistance should be suspected in patients with persistent mild hypercortisolism contrasting with an absence of clinical or metabolic symptoms. Abnormalities in the *NR3C1* gene that encodes the glucocorticoid receptor are associated with generalized glucocorticoid resistance. This rare condition is characterized by decreased tissue sensitivity to glucocorticoids, which, at the pituitary and hypothalamic levels, induce compensatory ACTH secretion and, consequently, biochemical ACTH-dependent hypercortisolism discordant with the absence of Cushing syndrome. The chronic increase in ACTH secretion is responsible for the development of adrenal nodules and hypersecretion of mineralocorticoid precursors and DHEA, which may induce hypertension, hypokalemia, and hirsutism. The spectrum of the disease is, however, very wide, and patients may be minimally symptomatic. Heterozygous *NR3C1* mutations have been identified in more than 5% of patients with incidentally-discovered moderate-sized adrenal nodules and an impaired 1-mg DST.[100] Genetic analysis for *NR3C1* mutations should therefore be considered in patients with mild ACTH-dependent hypercortisolism without specific clinical features of Cushing syndrome, especially in the presence of a moderate decrease in serum potassium associated with low plasma aldosterone and renin concentrations.

Differentiating Cushing disease From Ectopic Adrenocorticotropic Hormone Syndrome and Ectopic Corticotropin-Releasing Hormone Secretion

Epidemiology and Etiologies of Ectopic Adrenocorticotropic Hormone Syndrome.

The prevalence of ectopic adrenocorticotropic hormone syndrome (EAS) established from tertiary referral centers is 9% to 18% of cases of ACTH-dependent Cushing syndrome.[35,101] The vast majority of EAS cases occurs in adulthood, with pediatric and adolescent cases being the exception.[102] EAS results from unregulated ACTH secretion by tumors of various locations, and various degrees of histological differentiation and aggressiveness.[35] Some ectopic ACTH-secreting tumors, such as well-differentiated bronchial neuroendocrine tumors (previously called "carcinoids"), carry an excellent tumor prognosis.[103] These tumors usually exhibit indolent growth and may even be radiologically undetectable for months.[35,101,103] At the opposite end of the spectrum are aggressive neuroendocrine carcinomas associated with locoregional or distant spread.[35] Obviously, these tumors represent different diagnostic challenges. Their respective frequencies vary among series, possibly because of recruitment bias (e.g., cancer vs. endocrine departments). However, the proportion of differentiated neuroendocrine tumors recruited by endocrinologists has increased dramatically over the years.[35,101] Ectopic CRH-secreting tumors are very rare, corresponding to the same etiologies as ectopic ACTH syndrome, and most cases involve concomitant secretion of CRH and ACTH.[104] Rarer, challenging cases of exclusive CRH secretion have also been described.[105]

Clinical Presentation and Baseline Biochemical Investigations.

In patients with evident neoplastic disease treated in various hospital departments, there is no differential diagnosis issue with Cushing disease, and the main diagnostic problem is to not overlook EAS because classical features of Cushing syndrome (such as weight gain, buffalo hump, etc.) may be missing owing to the rapid development of intense hypercortisolism. In an endocrinological clinical setting, and although there is significant overlap in the clinical and biochemical presentation between patients with Cushing disease and EAS,[103] several characteristics can direct the diagnosis towards an EAS. Patients with EAS are significantly older and more likely to be male than patients with Cushing disease. The progression of symptoms is usually accelerated, and hypercortisolism is intense in EAS. Consequently, within months patients develop overt catabolic symptoms (profound muscle weakness, osteoporotic fractures), mild or absent weight gain,[35,101] hypertension, and profound hypokalemia owing to the saturation of the renal 11β-HSD type 2 by excess substrate. Large increases in UFC (>5-fold the normal range), serum cortisol (>1000 nmol/L), and ACTH (>150 pg/mL) concentrations are common.[35,101] Indeed, the pretest probability of Cushing disease in a middle-aged woman with ACTH-dependent Cushing syndrome of moderate biochemical intensity, without hypokalemia or major elevation of plasma ACTH, and having settled gradually over more than a year, is generally more than 90%.[106] This pretest probability may exceed the sensitivity and specificity of some dynamic tests.

Biochemical Investigations

General considerations. The rationale of dynamic tests to differentiate Cushing disease from EAS is to indirectly assess, *in vivo,* the differences in molecular equipment between adenomatous corticotrophs (which typically exhibit the "corticotroph phenotype") and ectopic ACTH-secreting tumor cells. The corticotroph phenotype is characterized by the presence of glucocorticoid receptors that retain the ability to inhibit ACTH secretion in the presence of high doses of dexamethasone; overexpression of the V3R receptor for vasopressin and aberrant expression of the V2R renal receptor for vasopressin and its pharmacological analog desmopressin; and overexpression of the CRH receptor.[97,98] Consequently, a clear suppression of cortisol production following a high-dose DST (HDDST) and an increase in plasma ACTH and cortisol concentrations following intravenous injection of CRH or desmopressin are expected in Cushing disease. Typically, ectopic ACTH-secreting tumors lack this molecular equipment and do not respond to the tests. However, well-differentiated neuroendocrine tumors may express the glucorticoid, V2R/V3R, and CRH receptors and, consequently, respond to tests in a similar way to corticotroph adenomas. Therefore, no single test is free of false positives and false negatives, and any test should be interpreted from a probabilistic perspective, (e.g., the stronger the response, the more likely the diagnosis of Cushing disease). One important caveat for any test is the cyclical Cushing syndrome that may occur both in Cushing disease and EAS, in which the response to tests during periods of tumor inactivity may reflect normal pituitary corticotroph function. Among other considerations, no large prospective study conducted in difficult cases has assessed the usefulness of tests in a "real-life" setting where available information (age, sex, intensity of hypercortisolism, etc.) affects the pretest probability, as mentioned previously. Lastly, time-consuming tests should not be performed in urgent cases where patients have intense hypercortisolism.

Tumoral Markers. An increased plasma concentration of POMC suggests the presence of an aggressive ACTH-secreting tumor such as a pituitary corticotroph macroadenoma or an ectopic ACTH-secreting tumor.[15] However, this assay is not widely available, and increased POMC concentrations are usually associated with obvious pituitary and ectopic ACTH-secreting tumors on imaging.[15]

Measurements of biochemical markers indicating the ectopic source of ACTH are not routinely performed but may be part of the workup for patients where there is a strong suspicion of EAS. These include calcitonin, plasma or urinary metanephrines, and urinary 5-hydroxyindoleacetic acid for ACTH-secreting medullary thyroid carcinoma, pheochromocytoma, and gut neuroendocrine tumors, respectively.[35,101] The measurement of plasma chromogranin, nonspecific enolase, and other nonspecific markers has been abandoned, given their poor diagnostic utility.

High-Dose Dexamethasone Suppression Test. The rationale for the HDDST is that the negative feedback control of ACTH is reset to a higher level than normal in Cushing disease. Consequently, cortisol levels may decrease after high doses of dexamethasone, contrary to what occurs in EAS. In the modern era, the time-consuming and cumbersome standard 2-day test combined with urine collection has been replaced by the overnight HDDST, which has been found to have equivalent diagnostic performance in a direct comparison of the two approaches.[107] Eight milligrams of dexamethasone are given orally as a single dose at midnight, and the 8:00 AM serum cortisol value the following morning is compared with that of the previous day. Although the test is usually well-tolerated, administering a large dose of dexamethasone in patients with intense hypercortisolism may worsen comorbidities, such as hyperglycemia, or precipitate steroid psychosis. In both older and more recent studies, a 68% to 71% suppression of plasma cortisol has been associated with 64% to 71% sensitivity and 99% to 100% specificity for the diagnosis of Cushing disease.[107,108] Consequently, the performance of the HDDST has been greatly questioned, and the test has been abandoned by several expert teams based on several arguments.[35,109,110] These include a complete overlap between the responses in Cushing disease and EAS, with a range of suppression from 0% to 99% in each clinical situation.[106] In the same vein, an Italian study evaluating the performance of the test by receiver operating characteristic analysis, showed that the results obtained using the percentage decrease in cortisol were not different from those

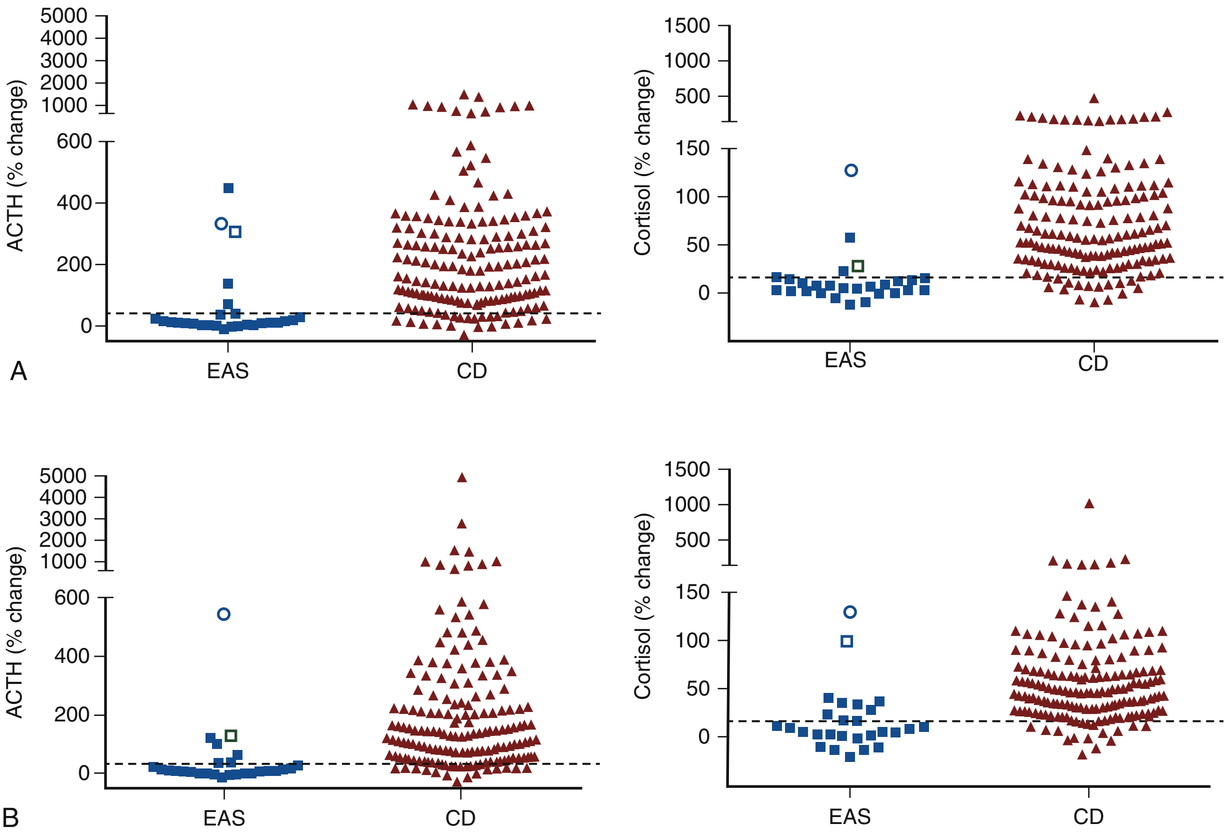

Fig. 7.11 Individual values of relative increases (%) in plasma cortisol and adrenocorticotropic hormone (*ACTH*) **A,** during the corticotropin-releasing hormone (*CRH*) test and **B,** desmopressin test in 167 consecutive patients with Cushing disease (CD) and 27 patients with ectopic ACTH syndrome (*EAS*). The open squares and open circles represent plasma cortisol and ACTH concentrations of two patients with EAS who responded to both the CRH and desmopressin tests. Dashed lines represent thresholds for the positive response to the tests. Note that no test allows complete differentiation between the two groups of patients. (Reproduced with permission from Frete C, Corcuff JB, Kuhn E, et al. Non-invasive diagnostic strategy in ACTH-dependent Cushing syndrome. *JCEM.* 2020;105:1-12.)

obtained by chance.[111] A large study also reported that the diagnostic performance obtained with a 30% plasma cortisol suppression following the LDDST was approximately the same as that of the HDDST.[112]

Corticotropin-Releasing Hormone Stimulation Test. The CRH test is probably the most widely used and has the best-documented performance for the diagnosis of Cushing disease. Synthetic ovine CRH or synthetic human CRH is injected intravenously at a dose of 100 µg or 1 µg/kg body weight. Response is assessed by measuring the percentage increase in circulating ACTH and cortisol concentrations at 15, 30, 45, and 60 minutes after administration of CRH as compared with baseline preinjection values. As the response occurs rapidly after CRH injection, several authors have proposed limiting blood sampling to the first 30 minutes.[108,113,114] The test can be performed irrespective of the time of the day and is well-tolerated, with very few and mild side effects (facial flushing, headaches). A positive response is highly suggestive of Cushing disease, although there is no universal consensus regarding the criteria for interpreting the test. In most large studies, the ACTH response was found to perform better than the cortisol response, and, using variable thresholds of a 35% to 105% increase in plasma ACTH, the test had 83% to 93% sensitivity and 90% to 100% specificity.[108,111,113,114] Other studies have stated that the cortisol response performs better than the ACTH response when using a threshold of a 14% increase.[113] In clinical practice, we recommend considering both the cortisol and ACTH responses. In the largest published study to date, which involved 167 patients with Cushing disease and 27 challenging cases of ectopic ACTH secretion, a combined response of 17% and 37% increase in cortisol and ACTH, respectively, was associated with a positive predictive value for Cushing disease of 97%[110] (Fig. 7.11). The stimulatory action of CRH can be strengthened by the synergistic effect of desmopressin, but the combined desmopressin-CRH test is rarely used.[115]

The Desmopressin Test. Desmopressin is a pharmacological analog of vasopressin that binds to V2R, and the rationale of the test is to take advantage of the aberrant expression of the V2R in adenomatous corticotrophs.[97,98] Desmopressin is injected intravenously at a dose of 10 µg, and response is assessed by measuring the percentage increase in circulating ACTH and cortisol concentrations 15, 30, 45, 60, 90, and 120 minutes after the injection as compared with baseline preinjection values. The test is well-tolerated with mild side effects (flushing, tachycardia, mild decrease in blood pressure, headache), but restriction of fluid intake for 12 hours is recommended to avoid water overload. In a metaanalysis, a positive response based mainly on predetermined arbitrary thresholds for ACTH and cortisol responses was observed in 84% of patients with Cushing disease, but also in 31% of the limited number of included patients with EAS, suggesting that the test had suboptimal specificity.[98] This may be because of the expression of vasopressin receptors in a number of well-differentiated ectopic ACTH-secreting tumors bias in published studies.[98,115] In the largest published study to date, involving 167 patients with Cushing disease and 27 challenging cases of ectopic ACTH secretion, a combination of cortisol response of 18% or more and ACTH increase greater than 33% showed approximately the same performance as the CRH test, with a 97% positive predictive value and only a slightly lower specificity (81% vs. 85%) (Fig. 7.11).[110]

Combination of Tests. In view of the limitations of single tests, the performance of at least two dynamic tests is recommended.[1,101] Concordant positive results reduce the risk of false positives. The combination of HDDST and the CRH test[1,101,108,116] has been the most accepted in this perspective. In a large study, the combination of the LDDST and CRH tests had similar diagnostic accuracy (sensitivity 94%, specificity 97%) to the combination of the HDDST and CRH tests.[112] Some groups have suggested performing the HDDST, CRH, and desmopressin tests as a trio[116] when pituitary imaging is not conclusive, whereas other groups that have abandoned the HDDST have proposed the combination of the CRH and desmopressin tests.[110] However, it should be kept in mind that, although positive responses to several tests clearly shift the probability in favor of Cushing disease, this does not formally exclude EAS.[110,111] In addition, the results of tests have been reported to be discordant in at least one in four patients.[35,101,110]

Pituitary Imaging. Pituitary MRI is the most useful imaging technique for the visualization of corticotroph adenomas. Because more than 80% of corticotroph adenomas are microadenomas, with a median size of 4 to 5 mm,[110,117,118] the technical aspects of pituitary MRI play an important role.[119] Despite optimal technique, it is classically accepted that standard pituitary MRI with spin-echo sequences and gadolinium enhancement identifies approximately 50% of corticotroph adenomas.[119] However, some studies have shown an improvement over time in the rate of detection to 71% to 81%, with refinements in MRI techniques and the growing expertise of dedicated neuroradiologists.[110,117,120] Alternative MRI protocols such as dynamic MRI, combining rapid and early image acquisition following a bolus injection of contrast medium, or fast spoiled gradient recalled echo, which permits imaging with 1-mm slice intervals, offer greater sensitivity for localizing corticotroph microadenomas. However, these techniques also yield more false-positive scans.[119] False positives, which are also observed with spin-echo sequences, include erroneous localization of pituitary adenomas in patients with Cushing disease or the suggestion of a microadenoma in a patient with ectopic ACTH syndrome.[103,120] The frequency of pituitary lures increases inversely with the size of the lesion and has been found in at least 10% of patients without pituitary disease.[99] Consequently, some algorithms recommend consideration of MRI as positive only when pituitary images suggesting an adenoma are greater than 6 mm.[1,101,121] This 6-mm threshold, which originates from a 1994 study,[99] has been debated[110] because it does not take into account more recent technological improvements in MRI.[117] Although lesions 2 mm or smaller should not be considered as positive, given the poor reliability of pituitary MRI at this size, analysis of qualitative characteristics of pituitary lesions by experienced radiologists/neurosurgeons is also a major contributor to the performance of pituitary MRI.[110,122] Increasing the strength of the main magnetic field to 3 Tesla (T) allows greater spatial resolution. However, definitive superiority of 3 T MRI over 1.5 T MRI has not yet been clearly demonstrated.[119]

Promising results have been obtained with positron emission tomography (PET)/CT using ^{11}C-methionine, an amino-acid tracer that accumulates in pituitary adenomas with a low grain uptake. The coupling of PET/CT with MRI, which is currently under evaluation, allowed localization of corticotroph microadenomas, invisible on MRI, with acceptable anatomical precision.[123] PET, using the more specific tracer CRH, has recently been studied using molecular imaging in a small number of patients and may pave the way for future imaging strategies.[124]

Bilateral Inferior Petrosal Sinus Sampling. ACTH is secreted into the two cavernous sinuses that drain into the inferior petrosal sinuses. Assuming that the secretion of normal corticotrophs is suppressed by chronic hypercortisolism, direct measurement of ACTH concentration in the petrosal sinuses after catheterization via the femoral and comparison of its concentration with that in a peripheral vein (central-to-peripheral plasma ACTH gradient) is therefore a direct way to demonstrate that the inappropriate ACTH secretion originates from

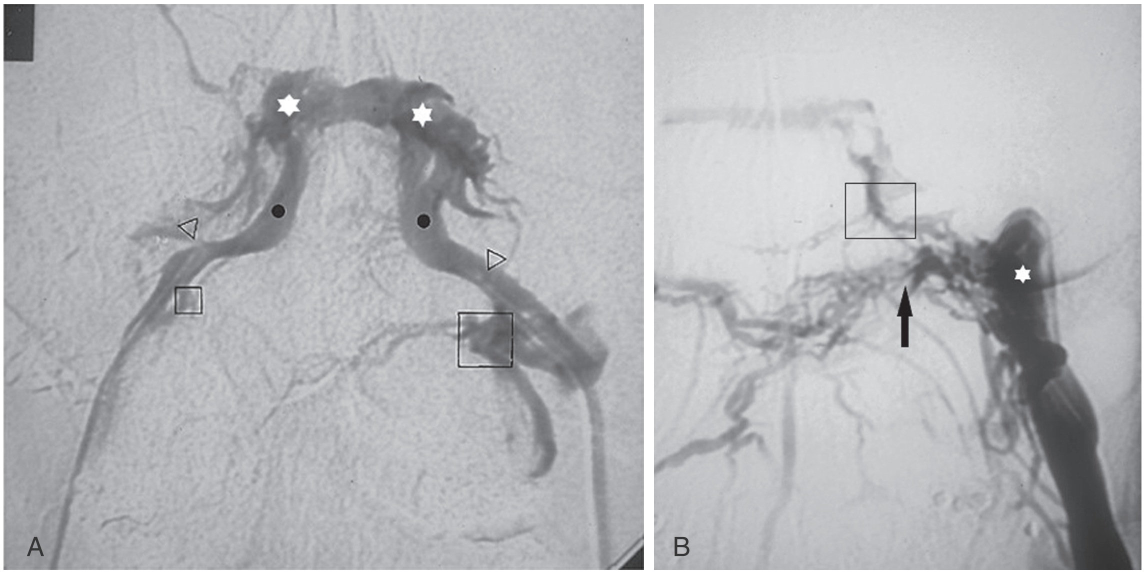

Fig. 7.12 Angiograms performed during bilateral inferior petrosal sinus (IPS) sampling. **A,** Adequate localization of the catheter tips (*arrow head*) in the "horizontal" part of the IPS. Note that the two IPSs have approximately comparable diameters. Dots: vertical part of the IPS situated just below the cavernous sinus (*star*). Square: Basilar venous plexus of the clivus that drains nonpituitary blood into the jugular vein. The correct localization of catheter tips prevents the dilution of samples by nonpituitary blood. **B,** Anatomical variant with atrophic left IPS (*square*) that cannot be catheterized. The catheter tip is located in the jugular bulb (*arrow*), allowing dilution of samples with nonpituitary blood, which may result in false negatives bilateral inferior petrosal sinus sampling results.

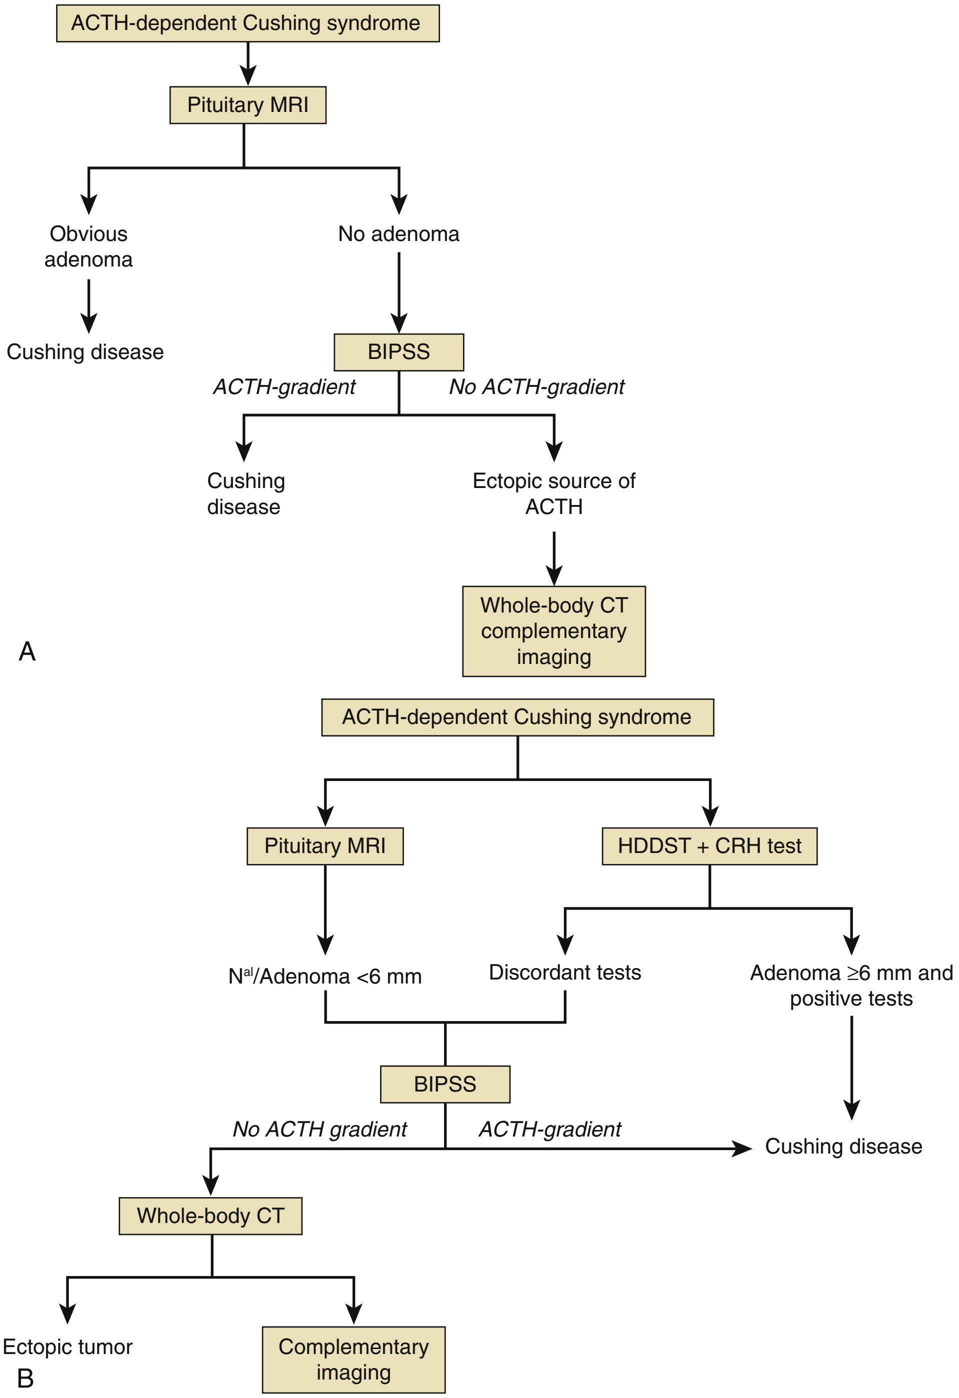
the pituitary. To overcome the pulsatility of ACTH secretion, which may result in the absence of a central-to-peripheral ACTH gradient,[125] additional blood samples are drawn at the three sites, usually, 2, 5, and 10 to 15 minutes following peripheral intravenous injection of 100 µg of CRH. Given that some pituitary corticotroph adenomas do not respond to CRH, or CRH may not be available, desmopressin may be used in place of CRH with approximately similar sensitivity and specificity.[125] Other studies have proposed simultaneous administration of CRH and desmopressin, with slightly different thresholds for analysis of the results.[126]

Adequate catheterization of inferior petrosal sinuses (in the "horizontal" segment; see Fig. 7.12) is of major importance to avoid dilution of ACTH in the petrosal sinuses by nonpituitary blood. Cavernous-inferior petrosal sinus venography must be performed during and at the end of the procedure to assess venous anatomy and to ensure correct localization of the catheter tips. In expert hands and following considerable experience, optimal catheterization of inferior petrosal sinuses is obtained in more than 90% of patients.[125] Transient otalgia during the ascent of catheters and groin swelling or hematoma are common. The incidence of serious adverse events, such as a cerebrovascular accident or transient cranial nerve palsy with experienced teams, is less than 1%.[127] To prevent deep venous thrombosis and pulmonary embolism, a rare event in experienced hands and with recent developments in endovascular materials, some groups, although not all, administer heparin for anticoagulation before the procedure.[125]

The universal criterion for the diagnosis of Cushing disease is a central-to-peripheral plasma ACTH gradient of 2.0 or more before CRH administration or 3.0 or more after CRH injection.[125,128] To date, BIPSS has the best performance for the diagnosis of Cushing disease, with sensitivities ranging from 85% to 100% and specificities from 82% to 100%. In 11 published monocentric studies enrolling at least 50 patients, the overall sensitivity based on 1309 patients with Cushing disease was 92%, and the specificity based on 97 patients with EAS was 96%.[125] The baseline sensitivity improved by 2% to 21% following CRH injection.[125,128] False negatives are more common and usually result from incorrect catheter placement or anatomical variations in venous drainage (Fig. 7.12) allowing dilution of pituitary blood with venous flow coming from other areas of the brain stem.[125,129] Expert analysis of angiograms should therefore be performed in conjunction with analysis of ACTH concentrations. Based on analysis of 501 procedures, a study identified that low ACTH concentrations in the petrosal sinuses (400 ng/L) associated with low central-to-peripheral ACTH gradients should raise suspicion of a false negative.[120] Prolactin measurement in inferior petrosal sinus blood samples has been proposed as a means of recognizing whether pituitary venous blood has been accurately sampled, with recalculation of central-to-peripheral ACTH ratios after normalization using central-to-peripheral prolactin ratios.[125] However, the criteria for interpretation vary between centers, and a degree of uncertainty remains.[130] Bilateral internal jugular venous sampling has the advantage of simplicity and has been proposed as an alternative to BIPSS.[131] However, the procedure has not gained wide acceptance, as its sensitivity is clearly inferior to that of petrosal sinus sampling. False positives occur rarely in patients with ectopic ACTH syndrome and are not always fully explained.[125,129] Aside from the rare situation of an ectopic CRH-secreting tumor that is stimulating pituitary corticotrophs,[105] an important prerequisite is the suppression of normal anterior corticotroph function by chronic hypercortisolism. Incomplete suppression of physiological corticotroph function in patients with EAS and intermittent/cyclical cortisol secretion, or following a previous treatment with anticortisolic drugs, may therefore result in false positives. It is therefore mandatory to perform BIPSS in a state of chronic hypercortisolism and to verify this with the help of routine biochemical tools.

The use of BIPSS to localize corticotroph microadenomas within the pituitary has been proposed based on the assumption that each pituitary half drains into the homolateral cavernous sinus. Consequently, an ACTH gradient of 1.4 or more between the right and left petrosal sinus would predict lateralization of the tumor and would favor a hemihypophysectomy in the case of negative surgical exploration.[132] However, venous drainage in the petrosal sinus is asymmetric in a number of patients,[133,134] and most subsequent studies have reported low accuracy that was sometimes no different from chance.[133,134] Using higher thresholds for the intersinus ACTH gradient[120] or restricting the analysis of this gradient to patients with symmetrical petrosal venous drainage resulted in a marginal improvement in performance.[133,134] The accuracy of cavernous sinus sampling for predicting the lateralization of corticotroph adenomas has been explored, but was not better than that of BIPSS.[133,134] In one series, hemihypophysectomy based on lateralization data was curative in only about 50% of patients.[134]

Overall Strategy for Differential Diagnosis. Several algorithms for the differential diagnosis of ACTH-dependent Cushing syndrome have been proposed (Fig. 7.13). However, a number of considerations need



ACTH-dependent Cushing syndrome
Pituitary MRI
Obvious adenoma
No adenoma
Cushing disease
BIPSS
ACTH-gradient
No ACTH-gradient
Cushing disease
Ectopic source of ACTH
Whole-body CT complementary imaging
A
ACTH-dependent Cushing syndrome
Pituitary MRI
HDDST + CRH test
Nal/Adenoma <6 mm
Discordant tests
Adenoma ≥6 mm and positive tests
BIPSS
No ACTH gradient
ACTH-gradient
Cushing disease
Whole-body CT
Ectopic tumor
Complementary imaging

Fig. 7.13 Three currently used algorithms for the differential diagnosis of adrenocorticotropic hormone (*ACTH*)-dependent Cushing syndrome in patients with a strong pretest probability of having Cushing disease. Owing to the absence of formal prospective studies comparing diagnostic algorithms with pertinent endpoints, various diagnostic strategies may be used to differentiate Cushing disease from ectopic ACTH syndrome. **A,** Because bilateral inferior petrosal sinus sampling (*BIPSS*) has the best overall diagnostic accuracy, this algorithm does not involve dynamic tests when pituitary magnetic resonance imaging is normal. **B,** Most frequently cited algorithm.

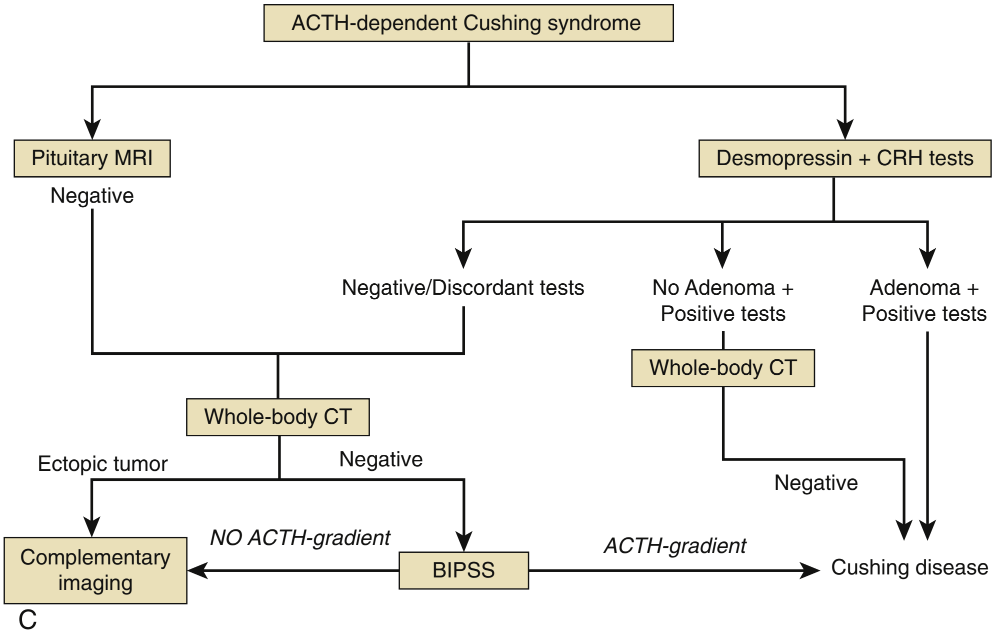

Fig. 7.13, Cont'd C, Alternative algorithm. The debated high-dose dexamethasone suppression test is replaced by the desmopressin test. A neck-to-pelvis thin-slice computed tomography scan is always performed before BIPSS to reduce the need for BIPSS in selected patients. *CRH*, corticotropin-releasing hormone. (**B** reproduced with permission from Lacroix A, Feelders RA, Stratakis CA, et al. Cushing syndrome. *Lancet.* 2015;386:913-27. **C** reproduced with permission from Frete C, Corcuff JB, Kuhn E, et al. Non-invasive diagnostic strategy in ACTH-dependent Cushing Syndrome. *JCEM.* 2020;105:1-12.)

to be taken into account. Firstly, there is no formal prospective study comparing diagnostic algorithms using relevant endpoints such as histological confirmation of the disease or surgical remission. Therefore, no algorithm can be recommended in an evidence-based manner. Secondly, no study has precisely evaluated the benefit and cost effectiveness of different strategies according to the global context, (e.g., the pretest probability of Cushing disease). For example, in a male patient with recent onset of intense hypercortisolism and with greatly increased plasma ACTH concentrations, the probability of EAS may be superior to that of Cushing disease, and performing thin-slice neck-to-pelvis CT first may be more relevant than pituitary MRI or a time-consuming battery of biological tests. Thirdly, the best diagnostic performance is obtained in expert centers with multidisciplinary expert teams.[122] This reinforces the importance of referring patients to expert centers. Fourthly, no algorithm can ensure 100% sensitivity and specificity, and thus all testing procedures should be considered to be probabilistic.[101]

Given the performance of BIPSS, some investigators recommend that all patients with ACTH-dependent Cushing syndrome and negative pituitary MRI undergo BIPSS. Although BIPSS has the best overall diagnostic accuracy, it is an invasive procedure requiring an expert center and is less readily available than noninvasive tests. In the same vein of reducing investigations, but at the opposite extreme in terms of invasiveness, some endocrinologists suggest performing pituitary surgery solely on the basis of an obvious adenoma (>6 mm) seen on pituitary MRI.[109]

The most recommended algorithm starts with a noninvasive approach and includes HDDST and CRH tests combined with pituitary MRI. BIPSS is scheduled when tests are negative/discordant, or if there is no obvious pituitary image on MRI (≥6 mm).[1,101,121] As discussed previously, the 6-mm criterion for positive MRI is debated.[110] Negative results of BIPSS should also be interpreted in relation to biochemical tests. Patients with frank positive responses to both CRH and HDDST have a high probability of having Cushing disease, and a nonsignificant central-to-peripheral ACTH gradient may reflect a BIPSS false negative. Transsphenoidal surgical exploration has been proposed for such patients[135] after negative results from extensive body imaging for an EAS.[35,101,136] Other groups have suggested performing three dynamic tests (HDDST, CRH, and desmopressin) and proceeding with pituitary surgery in patients with negative pituitary MRI when all tests are positive, without performing extensive body imaging, given the high likelihood of Cushing disease.[116,137]

Other publications have proposed modification of this "classical" algorithm to reduce the need for BIPSS while ensuring a 100% positive predictive value for Cushing disease.[110,122] This consists of pituitary MRI, desmopressin, and CRH tests in conjunction with expert radiological interpretation. If MRI shows a convincing pituitary image, and both tests indicate Cushing disease, the patient can proceed to surgery. Otherwise these tests were followed by modern thin-slice neck-to-pelvis CT that allowed rapid identification of an ectopic tumor. In patients with positive tests and negative CT, pituitary surgery was performed despite normal MRI. In the remaining patients with discordant or negative tests, BIPSS was performed if no lesion was seen at CT. The combination of tests, MRI, and possibly CT gave a correct diagnosis in 47% of a cohort including 167 patients with Cushing disease and 27 with challenging cases of EAS, halving the need for BIPSS in those patients where it is currently recommended.

TREATMENT OF CUSHING DISEASE

General Considerations

The duration of exposure to cortisol excess may play a major role in the persistence of comorbidities and reduced life expectancy after remission (see Prognosis for Cushing Disease: Persistent Morbidity and Mortality), suggesting that, once diagnosed, the rapidity with which

KEY POINTS

- Pituitary surgery performed by an expert surgeon with a high number of procedures is the only treatment that can offer a permanent cure with a low rate of adverse effects, and is the first-line treatment for CD.
- Given the frequency of recurrences, life –long follow-up is mandatory in patients in with post-surgical remission of CD
- The choice of second-line treatment when pituitary surgery has failed or is impossible is complex, must be individualized, shared by patients and discussed in an expert multidisciplinary team.
- Comorbidities may persist despite CD remission and explain at least in part the persistent deterioration in quality of life compared to other pituitary pathologies and long-term excess mortality. Treatment of the long-term sequelae of CD is therefore an important part of the treatment of the disease.

intervention controls hypercortisolism is of paramount importance. In addition, careful follow-up and treatment of persisting comorbidities after cure is an important component of therapy.[138] Resection of the "primary" tumor in the first instance, regardless of its etiology, is the rule in the treatment of Cushing syndrome.[138] Various secondary options are available when surgery fails, and significant advances in the development of pharmacological treatments have been made over the last decades. However, the treatment of Cushing disease remains complex, and, despite multiple treatments, biochemical control may not be achieved in up to 30% of patients, as has been reported in large multicenter cohorts.[139] This emphasizes that treatment of Cushing disease requires a dedicated expert team headed by a dedicated endocrinologist.

Pituitary Surgery. Surgical removal of the pituitary adenoma performed by an expert surgeon is the only therapeutic option that can offer definitive cure with a low rate of adverse effects, and is the first-line treatment for Cushing disease.[138]

Results and Safety. Some centers use, either routinely or in patients with more severe clinical features, preoperative medical adrenal blockade to attain a period of eucortisolemia for several weeks to several months before surgery.[140] The aim here is to allow reversal of some of the comorbidities of hypercortisolemia that may inhibit wound repair and cause other complications in the perioperative period. To date, this rationale is mainly empirical and mostly used in patients with severe Cushing disease. No difference in mortality and morbidity has been found between pretreated patients or patients operated on immediately.[140] The disadvantage of this strategy is that the normal corticotroph cells may be disinhibited by the time of surgery, so expected hypocortisolism after successful tumor resection does not occur, and this indicator of remission is thus unreliable.[140] Based on retrospective studies suggesting that preoperative anticoagulation reduces the risk of thromboembolic events, some groups recommend treating all patients.[40,41]

The goal of surgery is a selective and slightly enlarged adenomectomy with the preservation of as much normal pituitary tissue as possible. The procedure should therefore be performed by a neurosurgeon who is experienced in transsphenoidal surgery because the rate of surgical complications is less frequent than when performed by surgeons who seldom carry out this operation.[141,142]

Most pituitary corticotroph adenomas are microadenomas or small macroadenomas,[110,117] therefore, the transnasal transsphenoidal route is the rule in the majority of patients. A metaanalysis including more than 6000 operated patients concluded that endoscopic surgery achieves comparable results for microadenomas, and probably better results for macroadenomas, than does microscopic surgery.[143] If a tumor is identified during surgery, it is removed selectively, ideally including some tissue surrounding the adenoma (the "pseudocapsule"). If no tumor is visible, the pituitary gland is systematically explored after cross-incision. In patients in whom no adenoma is identified, several options are possible, among which partial/subtotal hypophysectomy, (e.g., removal of two-thirds of the lateral and posterior pituitary tissue), appears to be the best compromise between a high success rate and low rate of surgery-related hypopituitarism.[142] Some surgeons resect one half of the pituitary gland on the side of lateralization on BIPSS, but the accuracy of BIPSS for this purpose may not be better than chance, and, in one series, hemihypophysectomy based on lateralization data was curative in only about 50% of patients.[134]

Mortality rates associated with transsphenoidal surgery are approximately 1% to 2%.[138,142] Transient diabetes insipidus is probably the most common complication, being reported in more than 10% of patients. Other perioperative complications, including cerebrospinal fluid leak, meningitis, and profuse bleeding, occur in less than 10% of patients operated on by an experienced neurosurgeon. Permanent complications, such as persistent diabetes insipidus and injury to the optic nerve or nerves of the cavernous sinus (causing ptosis or diplopia), occur much less frequently. However, hypopituitarism, particularly GH deficiency, is common (53%–59% of patients), with other anterior hormone deficits occurring in approximately 35% to 49% of patients.[138,142] Such complications are more common after resection of larger tumors, after repeat surgery, and for small tumors, depending on the aggressiveness and extent of surgery. In a metaanalysis, the mean frequency of hypopituitarism was 7%, 20%, and 80% in patients who had undergone adenomectomy, hemihypophysectomy, and subtotal hypophysectomy, respectively.[142]

Variable criteria of various biochemical tests have been used to characterize postoperative remission.[141,142] This may explain the wide variations in reported remission rates, which ranged between 25% and 97% (mean 78%) in metaanalyses.[141,142] Various favorable prognostic factors have been established for postoperative remission.[118,144] These include microadenoma (vs. macroadenoma), lack of invasion of the dura or cavernous sinus, visualization of the adenoma during surgery, histological confirmation of an ACTH-secreting tumor, and the experience of the neurosurgeon. In rare instances, failure of pituitary surgery may be related to adenomas arising in ectopic sites such as the cavernous sinus or along the pituitary stalk. There is a continuing debate about whether visualization of pituitary microadenomas on MRI is a favorable prognostic factor for remission and whether to perform surgery in patients in whom no pituitary adenoma is seen on pituitary MRI.[118,142] We, and others, favor surgery once the diagnosis of Cushing disease is definitively established, based on the observation that the surgeon's eye is more accurate than MRI, and that the success of surgery does not differ based on the MRI results.[117,145] Based on series that showed a reduced rate of cure when MRI was negative,[118] "wait and see" alternative approaches, including pharmacological control of hypercortisolism and regular follow-up with pituitary MRI, have been suggested.[142,146,147] In our opinion, even though the rate of surgical success is slightly reduced in patients with a negative MRI, surgery should still be the first choice because it offers a definitive success rate of 70% to 85%,[117,118,142,145] and, importantly, all other therapeutic options remain possible in patients for whom surgery fails. However, the probability of identifying a pituitary microadenoma may be lower in patients with negative pituitary MRI, leading to more extensive pituitary resection and possibly to an increase in postoperative partial hypopituitarism.[145]

Despite initial remission, Cushing disease recurs in a significant number of patients. Although the criteria for remission vary among studies, two recent metanalyses of 17 to 68 studies with lengthy follow-up identified reported recurrence rates ranging from 5% to 48%, with a mean of 15% to 19%.[118,141] Recurrence occurred within 3 to 345 months (mean 47–51 months) following surgery. Most recurrences occur during the 15 years following surgery, but some recurrences were observed even 20 years after surgery, explaining an actuarial recurrence rate that may be as high as 25%.[118,141,142] Prolonged, if not lifelong, follow-up is therefore recommended.[138] The highest recurrence rates appeared to occur in studies where 10 patients or fewer were operated on per year, while the lowest rates were seen when 31 to 40 patients were operated on per year.[141] These data reinforce the recommendation that Cushing disease patients must be operated on by an expert surgeon.[138]

Postoperative Evaluation and Management. Various protocols are used at different expert centers. Some give higher than normal glucocorticoid replacement intraoperatively for 24 hours and then taper the dose within 1 to 3 days postoperatively. Where close perioperative supervision is possible, such glucocorticoid "cover" may be omitted, permitting a very early postoperative assessment of cure.[148] Morning (8:00 AM–9:00 AM) serum cortisol measurements 20 to 30 hours after the last glucocorticoid administration are the most commonly used parameter for early postoperative evaluation.[138] Other authors have proposed the use of salivary cortisol as a substitute for serum cortisol to characterize the postoperative status.[149]

What defines remission after transsphenoidal surgery is still debated, as are the prognostic factors for sustained remission and cure. As normal corticotroph cells are suppressed by the chronic hypercortisolism, it is expected that cortisol concentrations will be suppressed following complete resection of the corticotroph adenoma. Consequently, patients with hypocortisolemia less than 5 μg/dL (140 nmol/L) are classified as being in remission.[138] Complementary investigations (midnight serum or salivary cortisol, 24-hour UFC and 1-mg DST) in patients with nonsuppressed morning plasma cortisol will identify those with persistent hypercortisolism (surgical failure) and patients with eucortisolism. Patients with surgical failure and no tumor on pathology examination require reevaluation of the diagnosis of Cushing disease, including BIPSS if not performed before pituitary surgery. Of note, approximately 5% may experience delayed remission 2 to 3 months following surgery, possibly as the result of progressive necrosis of remaining tumor cells.[150]

Patients with documented eucortisolism after complementary investigations can be safely monitored without treatment and reevaluated initially at 3-monthly intervals. Although most patients will have recurrence, eucortisolism is compatible with sustained remission in some individuals.[138,151] Hypocortisolemic patients should be started on glucocorticoid replacement, with hydrocortisone at 12 to 15 mg/m^2 given in two to three divided doses, and the last dose should be taken no later than 5:00 PM to avoid long-term suppression of the HPA axis. Patients receiving hydrocortisone supplementation should be instructed that they are "dependent" on taking glucocorticoids and given appropriate counseling and education for adrenal insufficiency. Adrenal crises tend to occur early after remission of Cushing syndrome, which is likely the period of maximal HPA axis suppression.[152]

Patients should also be told to expect symptoms of malaise (asthenia, dizziness, joint and muscle aches, difficulty in concentrating) during the postoperative months, with these signs being interpreted as a withdrawal syndrome. These symptoms may persist up to 1 year, and no specific medication, including increasing the dose of hydrocortisone, has proven to be effective. The most important intervention is often continuous reassurance by the medical team.

Postoperatively, assessment for deficiencies in other pituitary hormones should be performed and the appropriate replacement regimen initiated as necessary. However, the results of evaluation of pituitary secretion in the early postoperative period may be difficult to interpret, as the suppressive action of chronic hypercortisolism on gonadotrophins, TSH, and GH secretion may take several weeks or months to resolve after remission.[51] Importantly, although GH supplementation in adult patients with persistent profound GH deficiency results in a significant improvement of quality of life and metabolic parameters,[153] other studies have warned of a possible increase in the incidence of metabolic syndrome.[154] There is no consensus on the timing of pituitary secretion testing, but is suggested to perform this evaluation when the patient recovers from corticotroph insufficiency and focus on the comparison of free T4 concentrations obtained within 1 month after surgery with preoperative T4 levels to identify hypothyroidism.[138]

Plasma sodium should thus be assessed several times during the first 2 weeks to diagnose hyponatremia, usually owing to transient inappropriate antidiuretic hormone secretion, which may occur in as many as 10% of patients.[138,142] Some glucocorticoid-induced comorbidities, including hypertension and glucose intolerance, may normalize rapidly during the postoperative period; therefore, treatments for these need to be reassessed, possibly after stopping medication. However, it is mandatory to accurately control cardiovascular risk factors during the postoperative period, given the persisting increase in frequency of acute events during the first postoperative year.[44] Similarly, deep vein thrombosis and pulmonary thromboembolism may be more frequent after pituitary surgery for Cushing disease.[40,42] There is no consensus regarding the indications for and duration of preventive anticoagulation treatment, which that may last for at least 2 months, according to some groups.[40,42]

Prediction of Postoperative Recurrence. Identification of early postoperative predictive factors of recurrence that can define high- and low-risk groups to adapt the duration and frequency of follow-up examinations has been an area of intensive research.

The lack of *USP8* mutations in adenomatous corticotrophs has recently been associated with long-term remission in a small cohort of patients, but requires additional studies.[20] Early postoperative corticotroph insufficiency is a well-established protective factor for recurrence but not an absolute criterion for definitive cure.[138,155-157] The duration of corticotroph insufficiency has also been identified as a significant predictor of recurrence.[155,157] In one study, recovery within 6 months, 1 year, and 2 years had a decreasing positive predictive value for recurrence of 64%, 61%, and 59%, respectively,[155] and no patient with corticotroph insufficiency of more than 3 years in duration experienced a recurrence.

The CRH test, performed in the early postoperative period, added no benefit for prediction of recurrence over early basal cortisol testing.[157] The desmopressin test has also been studied, based on the rationale that ACTH and cortisol responses are secondary to the stimulation of aberrantly expressed V2R, and that these receptors are expressed only in adenomatous corticotroph cells.[98] Although postoperative morning cortisol in patients with corticotroph insufficiency reflects the suppressed function of normal pituitary cells, a persistent "paradoxical" response to desmopressin would indicate the persistence of adenomatous corticotrophs that may induce late recurrence.[98] Two recent large studies have shown that the disappearance of the response to the test within 3 months following successful surgery is associated with a lower rate of recurrence in the long term.[98,156,158] The predictive value of a negative test was independent of other prognostic factors and showed a higher performance than did early postoperative morning cortisol.[156,158] Limitations of this test are that it is informative only in patients with a positive response before surgery, and that variable critical thresholds for the test are reported in different studies.

Postoperative Follow-Up. Various strategies have been proposed for long-term surveillance, but the lack of large-scale prospective comparative studies hampers attempts to define an optimal management strategy.[157] According to the Endocrine Society,[138] morning plasma cortisol concentrations should be measured before the morning intake of hydrocortisone every 3 months in patients with postoperative hypocortisolism, followed by a short Synacthen (Tetracosactrin, Cortrosyn) ACTH stimulation test when cortisol concentrations are greater than or equal to 200 nmol/L. Various strategies for tapering and discontinuing hydrocortisone are suggested when baseline or stimulated concentrations of cortisol are 450 nmol/L or higher. At this stage of recovery, we recommend precise evaluation of HPA function to ensure that the cortisol elevation is not associated with disease recurrence. LNSC or a 1-mg DST can be used to assess the precise status for this purpose and then serve as a new baseline for future assessments. Follow-up should rely on both clinical and biochemical investigations. Although appearance or progression of clinical symptoms, such as weight gain, worsening of hypertension, and hyperglycemia may indicate recurrence, monitoring commonly identifies the recurrence of biochemical abnormalities before that of clinical symptoms.[157] Biochemical evaluation is also warranted when patients are personally convinced that their disease has recurred, based on psychological perception of their state during the hypercortisolism phase.

Several studies suggest that an increase in 24-hour UFC is a late marker of Cushing disease recurrence, and that LNSC is more sensitive for diagnosing recurrence at an early stage. However, early-stage recurrence is a difficult diagnostic situation characterized by mild and widely fluctuating cortisol excess,[157,159,160] and multiple saliva samples may be necessary to ensure optimal diagnostic performance.[160] The accuracy of the 1-mg DST for this purpose has been less well documented,[70] but in our opinion is a valuable tool.[75]

Stimulation testing has also been proposed for diagnosis of recurrence at an early stage. A positive response to the desmopressin test has also been reported as occurring before the increase in UFC and sometimes before increases in LNSC.[159,161] A combined dexamethasone-desmopressin test (1 mg of dexamethasone, administered at midnight before desmopressin testing at 8:00 AM)[162] has also been proposed. The limited number of patients studied and the relatively short follow-up make it difficult to draw definitive conclusions on the usefulness of these investigations. Given its relatively poor sensitivity, pituitary MRI cannot be recommended as part of the regular follow-up in patients with postoperative remission.[138]

In summary, in the absence of consensus on the manner and duration of patient follow-up, the Endocrine Society recommends lifelong evaluation for all patients.[138] This should be specifically mentioned to patients. Individualized follow-up is still difficult to define, owing to problems in accurately stratifying patients at a low versus a high risk of recurrence. In our opinion, surgery performed in an expert center, histological confirmation of a corticotroph microadenoma, followed by a very low early postoperative cortisol level, prolonged corticotroph insufficiency, and lack of persistent postoperative response to the desmopressin test would favor a less rigorous follow-up schedule, with yearly examinations and a warning to patients that consultation is mandatory if clinical symptoms reappear after this period. More stringent follow-up would be preferable for other patients. Using a vigilant strategy to diagnose recurrence at an early stage is supported by small studies that demonstrate a clinical benefit of treating patients with early-stage recurrence despite normal UFC.[163]

Treatment Options After Postoperative Recurrence or Persistence

Second-line treatments include repeat pituitary surgery, pituitary radiotherapy, medical treatments, and bilateral adrenalectomy (BLA). The choice of second-line treatment varies based on several parameters, including the severity of hypercortisolism, pituitary oncological status, previous medical history, age and sex, concomitant medications and potent drug–drug interactions, patient factors such as a wish for fertility, efficacy profile, availability, and cost of treatments.[138] The choice between the different options is complex, as each modality has pros and cons, and there is no “one size fits all” treatment. Consequently, the therapeutic strategy should be discussed by an expert multidisciplinary team.[138] The complexity of second-line strategies is illustrated by a multicenter retrospective study that concluded that, at the last follow-up, biochemical control was not achieved, despite multiple treatments, in 30% of patients.[139] Apart from expert team discussions, shared decision-making with the patient is also highly recommended.[138]

Repeat Transsphenoidal Surgery. The indications for repeat pituitary surgery are slightly different in persistent hypercortisolism versus recurrent hypercortisolism. Persistence of Cushing disease corresponds to three main scenarios: removal of nonadenomatous pituitary tissue (with negative histology), incomplete removal of a microadenoma within the pituitary (with positive histology), or incomplete removal of an adenoma with extrasellar invasion. The expertise of the neurosurgeon performing the first surgery, the type of resection, and postoperative pituitary imaging need to be considered in this situation. Early repeat surgery is advisable in the two first scenarios; that is, if subsequent pituitary MRI is positive, or in those patients previously operated by a nonexpert neurosurgeon. Repeat surgery is not indicated in patients with cavernous sinus or massive dural invasion identified at the initial procedure.[121]

Recurrence of Cushing disease usually corresponds to regrowth of the adenoma from residual remnant cells at the site of the initial resection and the adjacent cavernous sinus dura. Repeat surgery is therefore an option because the adenoma can be found at, or immediately contiguous to, the site at which it was found originally.[121] Some teams, but not all, reoperate only if MRI if positive, as this is supposed to be a positive prognostic factor for the success of a second surgery. However, dural invasion may explain the lower remission rates and second recurrence following repeat surgery as compared to initial surgery.[118,164] More extensive resection is usual in repeat surgery, such as subtotal hypophysectomy, and morbidity, including hypopituitarism, is increased as compared to initial surgery.[118,142,164]

Pituitary Radiotherapy. Radiotherapy can be performed as a first-line treatment when surgery is not feasible, although it is mainly used as second-line treatment after surgical failure for its antisecretory effect or for oncogenic purposes in case of growing macroadenomas and large postsurgical remnants. Regardless of the technique used, the antisecretory effect is delayed, and it is necessary to first ensure that a medical treatment is effective and well-tolerated before planning radiotherapy.

Two types of radiotherapy may be performed: conventional or fractionated radiotherapy and radiosurgery. Both are performed with stereotactic planning to optimize the tumor dose and to minimize radiation to other areas. Conventional radiotherapy uses ionizing x-rays at a dose of 4500 to 5000 cGy, fractionated in 25 to 30 sessions over approximately 5 weeks. Radiosurgery applies a very high energy to the target in only one session. Radiosurgery uses various sources of radiation such as gamma rays from a Cobalt source (Gamma Knife) or from linear accelerators (LINAC, CyberKnife), or radiation with heavy particles such as protons. Proton beam therapy is associated with a sparing of the deeper tissues from unwanted radiation, a condition that might be preferable in children. One limitation of radiosurgery is the risk of inadvertent radiation-induced injury of cranial nerves (II, III, IV) or of the optic chiasm, in case of close proximity to the adenoma, which has been reported in 1.5% (range: 0%–6%) of cases. This does not occur with conventional radiotherapy, because of the fractionation of the dose delivered.[165] Because of its rapidity and convenience, radiosurgery has become a modality of choice for irradiation of small tumor remnants located in the sellar and parasellar regions. Two recent studies suggest that the efficiency of whole-sellar radiosurgery in patients with normal MRI is similar to that of patients with an identifiable target.[166,167] Therefore, conventional radiotherapy is currently used mostly in patients who are not candidates for radiosurgery owing to large tumor size or proximity to the optic structures (distance to the chiasm <5 mm).

A thorough metaanalysis published in 2018 reported biochemical remission rates of 68% (range: 46%–89%), with a mean time to remission of 15 to 24 months, using conventional radiotherapy as adjuvant therapy. Remission rates and time to remission for radiosurgery were roughly similar, at 66% (27%–100%) after 7 to 40 months.[165] However, similar to surgery, the efficiency of pituitary radiotherapy and comparison of the performance between conventional radiotherapy and radiosurgery is difficult because of highly variable criteria for remission of hypercortisolism and variable duration of follow-up across studies.[165] Although recurrence is considered rare following conventional radiotherapy, the largest series published, involving 278 patients treated by Gamma Knife, reported an 18% recurrence rate after apparent control of hypercortisolism, suggesting that care must be taken before drawing any conclusion regarding the long-term effectiveness.[166] Whether the rate of control of hypercortisolism is lower in radiosurgery but occurs earlier than with conventional radiotherapy remains debatable.

There is no consensus on prognostic factors for the success of radiotherapy, but, similar to pituitary surgery, radiotherapist expertise and treatment center patient volume positively influence remission rate.[165] A potential negative effect of ketoconazole treatment through an action at the pituitary level when given during radiosurgery has also been suggested.[168] Similar concerns have been reported for cabergoline during conventional radiotherapy.[169] Repeat radiosurgery in patients with Cushing disease that is refractory to both prior surgery and radiosurgery has been studied in a small series, and biochemical remission was achieved in approximately half of the patients.[170] However, 10% morbidity in terms of visual loss and diplopia was observed.

Tumor control, defined as a decrease in or stability of tumor volume on MRI, is similar between conventional radiotherapy and radiosurgery, and is achieved in approximately 90% of patients.[165]

The development of pituitary insufficiency is a frequent side effect of radiotherapy. The occurrence of new pituitary deficits is reported in up to 40% of patients after conventional radiotherapy[165] but may involve more than 70% of patients over the long term.[142] Furthermore, information on how pituitary function was evaluated, especially GH and sex hormones, is frequently lacking, making it possible that hypopituitarism was underdiagnosed in many studies. In a large multicenter Gamma Knife study, 25% of patients developed new hormone deficiencies during a mean follow-up of 5.6 years,[166] suggesting that the tolerance of radiosurgery is better than that of conventional radiotherapy. These results may be biased by a shorter follow-up than that cited for conventional radiotherapy.[165] The relative risk of developing a second intracranial tumor after pituitary radiotherapy is increased 3- to 4-fold, especially in patients irradiated at a young age, but with a low absolute risk (~1%) that is similar after conventional radiotherapy and radiosurgery.[171] An increased rate of ischemic stroke following radiotherapy has not been described in Cushing disease.[165] The possibility of a mild impact of radiotherapy on cognitive function is still a matter of debate.[168]

Therefore, continuous endocrine follow-up after pituitary radiotherapy remains critical (1) to assess the efficacy of radiotherapy after tapering of pharmacological treatments, assuming that after 2 to 3 years the probability of control of hypercortisolism with radiotherapy is low; (2) to detect and treat hypopituitarism; and (3) to ensure the absence of recurrence in cured patients, especially after radiosurgery.

Bilateral Adrenalectomy. BLA is currently performed using a laparoscopic approach. When performed in expert centers, the mortality rate is zero, and the morbidity is low.[172,173] The major advantage of BLA is its ability to provide immediate resolution of hypercortisolism and major improvement in clinical symptoms and quality of life.[173] Furthermore, its efficacy is permanent in almost all patients, and persistence of mild cortisol secretion owing to adrenal remnants rarely leads to recurrence of hypercortisolism.[172] No accurate study comparing clinical improvement following BLA versus radiotherapy and/or pharmacological strategies is available. The major drawback of BLA is the need for lifelong steroid replacement, with a risk of adrenal crisis that is equivalent to that observed in adrenal insufficiency resulting from other causes.[173] Patient education is therefore of primary importance after BLA.

The choice of BLA versus other second-line therapies must be debated in each individual case, but it is the treatment of choice in young women who are not cured following pituitary surgery and who wish to become pregnant, given the teratogenicity of available drugs. Outside of this situation, BLA is commonly proposed as the last option after numerous therapeutic attempts and many years after the diagnosis of Cushing disease.[173] This common strategy may favor persistent comorbidities because of the duration of exposure to cortisol excess.

The risk of typical Nelson syndrome, which includes the development of a pituitary macroadenoma, has been dramatically reduced with the availability of pituitary MRI.[174] The term "corticotroph tumor progression" is actually more appropriate, implying radiographic evidence of adenoma growth or identification of a new adenoma when previous pituitary imaging was negative. Using this definition, corticotroph tumor progression occurs in approximately 10% to 40% of patients[172,174] after a mean/median period of 2 to 3 years following BLA.[174] In one large study, corticotroph tumor progression occurred as early as 1 year after BLA, whereas its prevalence reached a plateau after 7 years.[175] Corticotroph tumor progression is not linked to *USP8* mutations[21] and has also been observed in patients treated with steroidogenesis inhibitors or glucocorticoid receptor antagonists.[146,147,176] Transformation into metastatic pituitary carcinoma is described rarely.[177]

All of the predictive factors identified for the development of corticotroph tumor progression, such as young age, presence of pituitary adenoma, and increased Ki-67 index, have given rise to contradictory publications.[174] The most consistent predictive factor is a marked increase in ACTH concentrations in the first year after BLA, although various thresholds have been proposed.[174,175] However, less than 50% of patients with these criteria will show tumor growth on MRI during a 10-year follow-up period.[177] Because BLA may be indicated in young women who are pregnant, the finding that pregnancy does not accelerate corticotroph tumor progression is important.[174,175] The protective effect of adjuvant radiotherapy for corticotroph tumor progression has been a matter of intense debate, but has not been confirmed.[174,175] In our experience, it should be considered before BLA in those patients with large and aggressive tumors.

There is no consensus on the monitoring of patients following BLA, which may include plasma ACTH measurement and, most importantly, pituitary MRI 6 to 12 months after BLA and then yearly. After

TABLE 7.5 Main Characteristics of Current Pharmacological Treatments for Cushing Disease

Target	Drugs	Usual dose range	Effectiveness	Time of action	Main adverse effects	Evidence/Comments
Pituitary-directed drugs	Pasireotide LAR	10–30 mg IM/4 weeks	26%–40%	Within 1 month	Frequent hyperglycemia, diarrhea, gallstones	Prospective randomized studies Works better in mild/moderate hypercortisolism Possible adenoma shrinkage
	Cabergoline	2.5–5 mg/week	28%–35%	Poorly known ≥1 month?	Asthenia, nausea, hypotension, psychiatric symptoms	Retrospective studies and limited cohorts Low-cost treatment Well tolerated
Adrenal-directed drugs	Ketoconazole	200–600 mg PO bid-tid	≥50%	2–3 days	Cytolytic hepatitis (severe <5%), gastrointestinal disorders, rash, male hypogonadism and gynecomastia	Retrospective studies Numerous drug interactions Need gastric acidity for absorption Reduced number of pills compared to metyrapone Preferred in woman over metyrapone
	Metyrapone	250–1000 mg PO qid	≥50%	Few hours	Nausea, dyspepsia, hirsutism/acne, hypokalemia, hypertension and edema at high dosage	Retrospective studies Very rapid effect Multiple pills in 3–4 daily intakes Issue in cortisol measurements for monitoring drug dosage Preferred in men over ketoconazole
	Mitotane	0.5–3.0 g PO tid	≥75%	≥3 months	Gastrointestinal disorders, asthenia/dizziness, neurological/cognitive disorders, hypercholesterolemia, biological cholestasis, hypogonadism, central hypothyroidism	Retrospective studies with few patients Frequent intolerance Almost constant adrenal insufficiency Long-term (years) avoidance of pregnancy after withdrawal
	Osilodrosat	2–30 mg PO bid	66%–81%	Days	Nausea, hypokalemia, hypertension, and edema at high dosage, hirsutism? Adrenal insufficiency	Prospective randomized studies/placebo control Issues in cortisol measurement for monitoring Reduced number of pills compared with metyrapone Frequent adrenal insufficiency during the titration period owing to the potency of the drug
	Etomidate	Various protocols ≤0.3 mg/kg/h	≤100%	Hours	Sedation, nephrotoxicity, myoclonus	Short-term treatment emergency treatment/oral therapy impossible Use in intensive care unit preferable
Glucocorticoid receptor–directed drug	Mifepristone	300–1200 mg PO bid	38%–60%	Days	Nausea, asthenia, metrorragia, endometrial hyperplasia, dizziness, hypokalemia	Open prospective study Efficiency mainly based on improved glycemia/hypertension Biochemical monitoring with cortisol impossible/Challenge of measuring disease activity Expensive (United States)

LAR, Long-acting release; *PO*, per os (by mouth).

5 to 7 years, the imaging intervals can be extended.[175] As the adenoma growth rate is usually slow, it is important to compare MRI scans with the first baseline examination.

Management of corticotroph tumor progression is variable and includes imaging surveillance for small tumors without mass effects. Surgery and radiotherapy alone and in combination are the most effective treatments, allowing tumor control rates of approximately 80%.[177] Medical treatments targeting the pituitary adenoma, such as dopamine and somatostatin agonists, have occasionally given good results, but only in isolated case reports.[174] Temozolomide treatment may be advisable in very aggressive tumors.[138,174]

Pharmacological Treatments

General Considerations. Pharmacological treatment is indicated mainly as first-line treatment in inoperable patients or as salvage treatment in rare patients with life-threatening intense hypercortisolism and as adjuvant treatment in patients with surgical failure or recurrence. In this last situation, medical treatment is usually a “bridging” therapy used to control hypercortisolism until a therapeutic option yields definitive cessation of hypercortisolism (repeat surgery, pituitary radiotherapy, BLA). Currently available drugs act through three modes of action: inhibition of cortisol synthesis, modulation of ACTH release by the corticotroph adenoma, and antagonism of cortisol at the level of its receptor.

Several considerations need to be taken into account regarding medical treatment. No drug has 100% potency, but all may induce adrenal insufficiency, and all have various side-effects (Table 7.5). Careful monitoring, including measurement of 8:00 AM plasma cortisol, is therefore necessary to anticipate and prevent acute adrenal failure. Spontaneous day-to-day fluctuations in cortisol production are also frequent in Cushing disease. Consequently, consistent large consistent changes in UFC are required to show the effectiveness of cortisol-lowering drugs and, conversely, to diagnose a true escape phenomenon.[73] All medications, with the exception of cabergoline, are contraindicated or not recommended in pregnant women.[138] Two main treatment strategies are currently employed, with no comparative data indicating the superiority of one strategy over the other. With the exception of glucocorticoid receptor antagonists, the "titration strategy" is the most commonly used and adapts the drug dosage to normalize biochemical markers such as UFC or serial daily measurements of plasma cortisol. The "block and replace" strategy is less frequently used and combines medical treatments at a dosage that induces the lowest cortisol concentrations achievable in association with glucocorticoid replacement therapy.[178] This strategy, which reduces the need for biochemical monitoring once the "blockade" is obtained, has been recommended as first-line therapy in situations of hospital overload, such as during active phases of the COVID-19 pandemic.[178] It should also be kept in mind that normalization of UFC does not imply restoration of the circadian rhythm of cortisol, as demonstrated by persistently elevated late-night salivary cortisol.[179,180] Recently published studies suggest that symptoms of hypercortisolism, such as hypertension, are better controlled in patients with both normalized UFC and midnight cortisol than in those patients with normalized UFC only.[180] Lastly, growth of pituitary adenoma remnants can be observed during all medical treatments and especially with those that do not target the pituitary adenoma.[142,146,147,176,181] Follow-up should therefore include pituitary MRI, bearing in mind that growth of remnants is usually a very slow process. Some authors take advantage of this situation and delay repeat pituitary surgery until a convincing MRI image is found in patients treated with steroidogenesis inhibitors following unsuccessful first surgery.[147]

Pituitary-Directed Drugs. Although inhibition of adenomatous ACTH secretion is ideal from a pathophysiological standpoint, its effectiveness remains only moderate because it depends on the presence and functionality of target receptors in the adenoma. To date, there are no predictive factors of their effectiveness, so a "trial-and-error" approach is required. Pituitary-directed drugs can induce tumor shrinkage and are an option when there are concerns about the oncogenic characteristics of the corticotroph adenoma.

Somatostatin Analogs

Pasireotide is a multireceptor-targeted somatostatin analog with a high binding affinity for the SSTR5 subtype that is expressed in approximately 30% of corticotroph adenomas.[142] Administered subcutaneously, twice-daily, in a large double-blind randomized trial, pasireotide was able to normalize UFC after 3 months in 26% of patients and improve both their clinical symptoms and quality of life.[182] Normalization of UFC was achieved approximately half of the patients with mild hypercortisolism (UFC <2 times the upper limit of normal [ULN]) in a second large trial using a long-acting version of pasireotide administered monthly via intramuscular injection.[183] A decrease in adenoma volume (≥20%) was observed in roughly half of the patients with evaluable tumors, whereas it increased in 10% of patients during the 12-month study.[183]

The main adverse effect associated with pasireotide is the occurrence of hyperglycemia in about 75% of patients, which appears within 2 weeks of starting treatment.[182,183] Its intensity is highest in older and already glucose-intolerant patients and diabetic patients. This side effect is independent of the control of hypercortisolism and is secondary to the inhibition of secretion of insulin and incretins.[142] Anticipation of this side effect with an adapted diet and careful monitoring of hyperglycemia are therefore mandatory. First-line treatments for pasireotide-induced hyperglycemia include metformin, glucagon like peptide 1 agonists, or dipeptidyl peptidase 4 antagonists.[142]

Dopamine Agonists

Cabergoline is a dopamine agonist that targets the type 2 dopamine receptor expressed in approximately 60% of corticotroph adenomas.[142] In the largest multicenter retrospective survey performed to date, normalization of UFC was observed in 40% of 53 patients treated with cabergoline as monotherapy in the short term and in 28% of patients in the long term.[184] The relatively moderate dosage median dosage needed to control UFC (2.5 mg/week), together with reports of corticotroph insufficiency during cabergoline treatment, suggests that some corticotroph adenomas may be exquisitely sensitive to the drug. However, up to one-third of patients who are initially responders can experience definitive escape from the treatment.[142] The delay in the action of cabergoline is not well known, but results from a 6-week prospective study suggest that its cortisol-lowering effect may be a slow process.[185] In some cases of corticotroph macroadenomas an antitumor effect has also been noted.[186] Adverse events may occur, including nausea, vomiting, and orthostatic dizziness. Rare impulsivity disorders have been recognized in patients treated for hyperprolactinemia and should be sought during questioning. Lastly, most studies of cabergoline therapy for hyperprolactinemia have provided reassurance with regard to the occurrence of carcinoid valvulopathy.[186] Overall, there appear to be several benefits of cabergoline, including its low cost, oral route of administration, and good tolerance.

Adrenal-Directed Drugs

Ketoconazole. Ketoconazole inhibits the enzymes CYP17A1, CYP11A1, and CYP11B1.[187] It is used orally at daily doses ranging from 400 to 1200 mg taken in two divided doses.[187] For optimal absorption, the presence of gastric acidity is necessary, and thus concomitant use of proton pump inhibitors may reduce its effectiveness. Small studies have suggested that the nadir of cortisol is obtained after 2 to 3 days of treatment.[188] In the largest retrospective study of ketoconazole in the treatment of Cushing disease,[189] normalization of UFC associated with clinical improvement was obtained in 49% of 200 patients, at an average dose of 700 mg/day of ketoconazole. Baseline UFC was not a predictor of efficacy, but this low dosage suggests frequent undertitration and that the efficacy of ketoconazole may have been underestimated. Indeed, a higher rate of control of hypercortisolism of various causes was observed with adequate and careful titration in single-center series.[142] Escape from treatment occurs in less than 15% of cases.[142,189] A transient and mild increase in liver enzymes is seen in approximately 15% of patients and usually occurs during the first 2 months of treatment or after increasing the drug dosage.[189,190] Major cytolytic hepatitis occurs in only 2.5% to 5.5% of patients. This idiosyncratic event is unrelated to the drug dosage and is reversible with withdrawal of the drug.[189,190] Frequent measurement of hepatic enzymes during the first weeks of treatment is mandatory. Other common adverse effects include gastrointestinal intolerance, male hypogonadism, and gynecomastia, secondary to the inhibition of testicular steroidogenesis that occurs at lower doses than those required to inhibit cortisol production.[187] Although the exact prevalence of ketoconazole-induced male hypogonadism is unknown, this adverse effect suggests that the drug should be preferentially used in women. Importantly, ketoconazole is a potent inhibitor of CYP3A4 and thus may modify the bioavailability of numerous drugs that are metabolized by this enzyme.[187] A detailed analysis of the patient drug profile is thus mandatory before commencing treatment with ketoconazole, as well as close monitoring and dose adjustments of the associated drugs.

Metyrapone. Metyrapone, which mainly inhibits the CYP11B1 and CYP11B2 enzymes,[187] is notable for its rapid onset of action, with a nadir of cortisol levels obtained approximately 2 hours following a single dose.[191] Because of the short half-life of the drug, it should be administered in three to four daily divided doses.[192] A large retrospective UK survey reported control of hypercortisolism in approximately 50% of patients.[192] The average dose of metyrapone was only 1350 mg/day, indicating probable undertitration and underestimation of treatment efficacy. Nausea and abdominal discomfort are the most frequent side effects of the drug. Metyrapone causes the accumulation of steroids upstream from the 11β-hydroxylase blockade, including mineralocorticoids that can be responsible for edema, hypokalemia, and hypertension at high dosages of the drug, and of adrenal androgens, which are responsible for hirsutism and acne in women.[142] The dramatic increase in the immediate cortisol precursor 11-deoxycortisol, which is structurally similar to cortisol, interferes with many commercial cortisol immunoassays, leading to an overestimation of cortisol levels.[187,191] It is therefore essential to monitor the cortisol response using more specific laboratory methods, such as LC-MS/MS.

Mitotane. Mitotane is an adrenolytic drug that inhibits multiple enzymatic steps of cortisol synthesis, including 11β-hydroxylase and P450 side-chain cleavage. In addition, mitotane at relatively high dosage induces cellular necrosis, leading to “chemical adrenalectomy.” A high rate of control of hypercortisolism and improvement in clinical symptoms is therefore obtained.[142] However, the anticortisolic effect is delayed for a median of 6 months, meaning that mitotane used in monotherapy is unsuited to situations requiring rapid control of hypercortisolism.[146] Mitotane has a long half-life owing to its accumulation in adipose tissue, but adrenal insufficiency may be reversible several years after cessation of treatment.[146] Because mitotane is a potent enzyme inducer (CYP3A4), the required doses of hydrocortisone supplementation may need to be increased by approximately one-third in some patients.[142]

A lower dosage of mitotane is required for treatment of Cushing disease than for treatment of adrenocortical carcinoma, and measurement of circulating concentrations of mitotane may help to target the titration of the drug.[146,187] In the largest single-center series, control of hypercortisolism was achieved in 72% of patients with a mean dose of 2.6 g/day.[146]

Mitotane leads to an increase in levels of CBG and therefore an increase in serum cortisol concentrations. Cortisol monitoring should thus be performed by measurement of UFC or LNSC. The main limitation of mitotane is the frequency of adverse effects, including gastrointestinal disorders, asthenia, neurological and cognitive disturbances, increased liver enzymes, hypercholesterolemia, thyrotroph insufficiency, male hypogonadism, and ovarian cysts.[142,146,187,193] Up to 30% of patients with Cushing disease may discontinue treatment because of drug intolerance.[142,146] Lastly, mitotane is a potent teratogen, and pregnancy should be avoided before clearance of circulating drug.

Osilodrostat. Osilodrostat is a more potent inhibitor of CYP11B2 and CYP11B1 than metyrapone, with a prolonged half-life compared to metyrapone allowing two doses per day. In a 22-week, open-label, prospective study (LINC-1), osilodrostat normalized UFC in 79% of a small cohort of patients with Cushing disease.[179] Interestingly, the dosage of the drug could be decreased in some individuals in the long term, during the extension phase of the study, while maintaining adequate control of hypercortisolism. In a recently published large-scale phase 3 study (LINC-3), at least 66% of patients with Cushing disease normalized UFC for at least 6 months of treatment, and approximately 10% more patients had a decrease in UFC greater than 50%.[181] Clinical symptoms and quality of life improved in parallel with the reductions in UFC. The most common adverse events were generally mild and included nausea, abdominal discomfort, and headaches. Side effects related to the production of steroids upstream of the pharmacological blockade, such as hypokalemia, hypertension, and hirsutism in women, were noted in 10% of patients. Importantly, because of the potency of the drug, hypocortisolism occurred at variable intensity in half of patients in the short and mid-term.[181] Adrenal insufficiency should therefore be anticipated during osilodrostat treatment by regular 8:00 AM plasma cortisol measurements, appropriate patient education, and prescription of hydrocortisone supplementation to be taken if needed.

Levoketoconazole. Although ketoconazole comprises a racemic mix of two enantiomers (an L-form and a D-form), levoketoconazole is a pure L-enantiomer that may possess higher potency as a steroidogenesis inhibitor than ketoconazole, allowing a lower drug dosage to be used. In addition, levoketoconazole has reduced liver exposure and interferes less with bile-acid synthesis than ketoconazole, hypothetically resulting in a minimal rate of hepatic dysfunction.

In a recently published multicenter phase III study in patients mostly suffering from Cushing disease,[194] 31% of the 94 patients had normalized UFC at the end of a 6-month maintenance phase, and the response rate was 49% in the 39 patients who had an initial UFC greater than two times and less than five times the ULN. Interestingly, testosterone concentrations were not reduced in men. Transaminases reversibly increased by more than three times the ULN in 11% of patients and more than five times the ULN in 3% of patients. These results are quite similar to those obtained with racemic ketoconazole, and in the absence of a head-to-head trial it is difficult to know whether levoketoconazole is superior in terms of efficacy and safety. Future studies may provide more data on the benefits of this new drug for Cushing disease.

Etomidate. Etomidate is an anesthetic drug administered intravenously in a polyethylene glycol solution that strongly inhibits 11β-hydroxylase, leading to a rapid decrease in cortisol production. Etomidate is usually used for several days while waiting for another intervention in patients with life-threatening hypercortisolism who are unable or unwilling to tolerate oral therapy, such as patients with acute steroid psychosis. Several protocols have been published using etomidate at variable dosages and using a titration procedure (implying four daily serum cortisol measurement) or a “block and replace” regimen.[195,196] Relatively high doses (0.3 mg/kg/h) usually decrease cortisol levels within hours but induce some degree of sedation and are preferably performed in an intensive care unit (ICU) setting. An alternative and convenient protocol, usable outside the ICU and involving reduced dosage of etomidate at 0.020 to 0.030 mg/kg/hour with daily increments of 0.010 mg/kg/hour until a morning cortisol value of 500 nmol/L is achieved, was recently published, and was able to control hypercortisolism within 3 days.[197] Similar to the case of metyrapone and osilodrostat, which inhibit 11-β-hydroxylase, cortisol immunoassays that have some degree of crossreactivity with 11-deoxycortisol may overestimate true cortisol concentrations. Other possible adverse effects include nausea, vomiting, kidney dysfunction, and myoclonus.

Glucocorticoid Receptor–Directed Drugs

Mifepristone is a competitive glucocorticoid receptor antagonist that inhibits cortisol action by binding to its cognate receptor. Mifepristone is not a selective antagonist and also binds to the progesterone receptor. The SEISMIC study evaluated the effect of mifepristone monotherapy in 50 patients treated for at least 30 days and reported an improvement in glucose tolerance and hypertension in 60% and 38% of patients, respectively.[176] In a long-term safety extension study, a beneficial effect on weight loss and other clinical features of Cushing syndrome persisted in patients who remained on therapy for 2 years.[198]

Importantly, by blocking the glucocorticoid receptor, mifepristone increases the secretion of ACTH and consequently increases cortisol concentrations, despite reduced access of cortisol to target tissues. Consequently, evaluation of the efficacy and titration of the drug is complex and is exclusively based on clinical symptoms and intermediate biochemical markers such as blood glucose, whereas serum and urinary measurements of cortisol are useless. This exclusively clinical approach to titrating mifepristone may lead to persistence of some degree of hypercortisolism and, conversely, difficulty in diagnosing hypoadrenalism because cortisol concentrations are not low in these patients. When hypoadrenalism is suspected, mifepristone treatment should be temporarily interrupted, and dexamethasone should be given in higher than normal replacement doses. Adverse effects of mifepristone include metrorragia and endometrial thickening in 20% of patients, which are secondary to antagonism of the progesterone receptor.[176] The increase in cortisol concentration may also exceed the capacity of the renal 11-βHSD enzyme to convert cortisol to metabolically inactive cortisone, and cortisol excess can stimulate the mineralocorticoid receptor, leading to hypokalemia, edema, and hypertension.

Combination of Medical Treatments

Medical treatments can be used in combination to increase their potency and/or reduce their dosage, as well as to limit the adverse effects of a given drug. Various combinations have been described, such as ketoconazole and metyrapone, that act on different target enzymes of adrenal steroidogenesis,[142,187,199,200] or steroidogenesis inhibitors combined with centrally-acting drugs such as pasireotide and cabergoline.[142,184]

Future Medical Treatments

Medical therapy for Cushing disease is an active area of research, and many novel and promising therapeutic targets for the treatment of patients with Cushing disease are currently being investigated, such as drugs targeting the tumoral corticotrophs, the MC2R ACTH- and glucocorticoid-receptor.[201] This research will be enriched by ongoing molecular studies of corticotroph tumors using modern pangenomic approaches (see Etiology).

PROGNOSIS FOR CUSHING DISEASE: PERSISTENT MORBIDITY AND MORTALITY

Remission or cure of Cushing disease is followed by clinical improvement. However, comorbidities may not be completely reversible, despite prolonged biochemical remission. Evaluation and treatment of the long-term negative effects of chronic hypercortisolism are therefore an important part of treatment to reduce morbidity, improve patient quality of life, and, hypothetically, reduce the long-term excess mortality associated with Cushing disease.

Metabolic Syndrome and Cardiovascular Risk

A decrease in body weight and fat mass is usually seen 6 to 12 months after successful treatment of Cushing disease. However, central obesity and increased total and visceral fat remain increased several years after remission,[47,54,202] and a number of patients maintain an unfavorable metabolic profile with an increased prevalence of diabetes and dyslipidemia.[29,33] The persistence of altered body fat distribution plays a key role in the maintenance of metabolic syndrome and is associated with a persistent state of low-grade inflammation.[202] GH supplementation may increase the incidence of diabetes and cardiovascular disease and should be carefully monitored.[154]

An improvement in blood pressure occurs in a majority of patients, but hypertension may persist in at least 30% of patients.[38] Persistence of hypertension has been attributed, at least in part, to microvascular remodeling and persistent abdominal obesity with insulin resistance. The prevalence of atherosclerotic plaques in the coronary and carotid arteries is increased even several years after cure as compared with control populations.[29,47,48]

Several studies suggests that the duration of hypercortisolism is a predictor of the persistence of cardiovascular risk factors and hypertension.[47,203] Importantly, the increased morbidity owing to thromboembolism, stroke, and myocardial infarction was found to be sustained, especially during the first year after cure.[43,44] Similarly, the procoagulative phenotype was not fully recovered 1 year postcure.[42]

Muscle

The natural history of muscle function following cure of Cushing disease is unclear. On MRI, patients may still show reduced limb skeletal muscle mass in the midterm and altered muscle function and muscle quality resulting in decreased muscle strength in the long term.[28,142,204]

Bone Disease

Most studies suggest a relief from glucocorticoid-induced suppression of bone formation following resolution of hypercortisolism with an early increase in plasma osteocalcin, rapid improvement of bone microarchitecture, and major improvements of bone mineral density, both in adults and children/adolescents.[29-31] However, 4 to 5 years may be needed to achieve full recovery, and a subset of patients in long-term remission show persistently lower bone mineral density than controls.[30] This may more specifically concern patients who experienced longstanding hypercortisolism, postmenopausal women, patients with associated hypopituitarism, or those who were treated with an excessive dose of hydrocortisone replacement.[54,202] Acquired spinal damage, including vertebral collapse and geometric abnormalities, persists after remission. A significant decrease in the fracture rate following remission of endogenous hypercortisolism has been described, but the data are scarce.[30] Of note, patients with previous fractures are predisposed to develop new fractures, despite remission, confirming that a history of fractures is a hallmark of skeletal fragility. Overall, considering the uncertainties of the natural history of bone disease following remission, an individualized approach is recommended. This includes detailed fracture assessment with lateral imaging of the spine, evaluation of bone mineral density and trabecular bone score, adequate calcium and vitamin D intake, avoidance of postsurgical excessive glucocorticoid supplementation, and personalized follow-up based on the results of the bone evaluation.

Mood and Cognitive Function

Significant improvement of psychopathology occurs rapidly following successful surgical treatment of Cushing disease or after reduction of hypercortisolism by pharmacological means.[34] However, patients with a previous history of Cushing disease show an increased prevalence in psychopathology symptoms, maladaptive personality, and mental exhaustion associated with a prolonged recovery time after mentally strenuous tasks. Long-term residual cognitive impairment, independent of coexisting chronic fatigue, affective disorders, or associated pituitary deficits, has been reported in several studies[36,205] and is more pronounced than in patients treated for nonfunctioning pituitary adenomas. Although several brain imaging studies have shown improvement in atrophy of key brain areas following remission, persistent structural and functional abnormalities have been described, such as decreased hippocampal volume at MRI and reduced functional responses in the prefrontal cortex in patients with severe verbal and visual memory impairment.[37] Overall, chronic hypercortisolism may have irreversible effects on the central nervous system. An increased rate of suicide has been reported in patients cured of Cushing disease.[206]

Autoimmunity

Cortisol excess inhibits the immune system. Following remission, a rebound in autoimmunity may be observed. Preexisting autoimmune diseases may become active again, and new onset of autoimmune diseases may also occur, with autoimmune thyroiditis being the most frequent endocrine disorder observed.[142]

Quality of Life

Health-related quality of life (QoL) analyzed with nonspecific and specific questionnaires[207] improves after remission. However, large cross-sectional studies report long-term residual impairment in physical and social functioning, as well as limitations in the ability to perform usual activities of daily life, owing to physical and emotional problems, pain, fatigue, sleep problems, and reduced vitality.[36,208] Postoperative hypopituitarism may also be detrimental to the QoL. Together with the residual psychological and cognitive impairments, decreased perceived health-related QoL has significant social and economic consequences, such as an inability to return to work.[208] Interestingly, patients with a history of Cushing disease report more negative illness perceptions compared with patients with other chronic diseases.[209]

Mortality in Cushing Disease

In the original publication by Harvey Cushing in 1932, the median survival in untreated patients with Cushing disease was less than 5 years, with the main causes of mortality being cardiovascular complications, including stroke and myocardial infarction. Multiple retrospective, nationwide, single and multicenter cohort studies have characterized the standardized mortality ratios (SMRs) in Cushing disease compared with both the general population and to patients with other types of pituitary adenomas or causes of Cushing syndrome. Persistent or recurrent Cushing disease after pituitary surgery confers a high risk of mortality that is mainly attributed to cardiovascular disease and infection, as compared to patients in remission. In a metaanalysis of eight studies,[45] the pooled SMR for patients with persistent or recurrent disease was 4.6 (95% confidence interval [Cl]: 2.9–7.3), compared with an SMR of 2.5 (95% Cl: 1.4–4.2) for patients in remission. Although remission is associated with a reduction in SMR, several studies report that it remains increased.[45,206,210,211] Furthermore, patients treated for Cushing disease have increased mortality compared with patients treated for other types of pituitary adenomas or patients with Cushing syndrome owing to adrenal causes.[211] In a multicenter study[210] analyzing long-term survival of patients in remission for at least 10 years, those who achieved remission after pituitary surgery alone had long-term survival comparable to that of the general population (0.9; 95% Cl: 0.6–1.5), whereas patients needing multiple treatments, probably reflecting disease that was more difficult to cure and prolonged exposure to cortisol excess, had a persistently increased SMR (2.6; 95% Cl: 1.9–3.6).[210] In support of this, mortality data from 346 patients over 31 years of follow-up identified that the length of exposure to hypercortisolism was associated with increased risk of death.[203] Other factors associated with increased mortality include older age at diagnosis, male gender, depression, and persisting cardiovascular risk factors such as diabetes and hypertension, and are independent predictors of mortality in most studies.[45,203,210]

Implications for Treatment and Long-Term Care

Taken together, these data highlight the importance of limiting the time of exposure to cortisol excess, emphasizing the importance of early diagnosis, choosing aggressive intervention, and attempting to perform, whenever possible, pituitary surgery as a first-line treatment. In patients with persistent disease or recurrence, hypercortisolism should be controlled as effectively and as soon as possible. Aside from rapid and effective treatment of hypercortisolism, the treatment of persistent comorbidities after cure represents an important therapeutic aspect, and aggressive treatment of hypertension, dyslipidemia, and other cardiovascular risk factors is warranted.[138] In patients with residual adrenal insufficiency, adequate adjustment of the hydrocortisone dose is important to avoid prolonging hypercortisolism, reduce the risk of infections, and allow healing of comorbidities. In addition, treatment of physical comorbidities may contribute to improvement in perceived quality of life. However, there is no effective therapeutic strategy for cognitive deficits except for psychological support and interactions with patients through membership in dedicated associations.

SPECIAL CONDITIONS

Cushing Disease as an Emergency Condition

Undiagnosed longstanding Cushing syndrome or intense hypercortisolism, a condition that is mostly seen in patients with EAS but also in a subset of patients with Cushing disease, is a life-threatening condition in the short term. In such instances the catabolic and metabolic symptoms are exacerbated, including bedridden status owing to profound myopathy and osteoporotic vertebral fractures, severe hypertension and acute heart failure, profound hypokalemia and major hyperglycemia, severe infections caused by bacterial, fungal, and opportunistic pathogens, pulmonary embolism, peritonitis as a result of gut perforation, and untreatable psychosis.[35]

This emergency scenario requires several tasks to be performed simultaneously in the setting of intensive care in collaboration with experienced endocrinologists. Firstly, rapid and systematic evaluation of comorbidities must be performed, and preventive and curative treatments of these comorbidities must be started simultaneously.[35] Management should combine specific treatments of morbid conditions, anticoagulation, and prophylaxis of *Pneumocystis jirovecii* pneumonia with sulfamethoxazole-trimethoprim.[138] At the same time, the diagnosis of Cushing disease must be conducted, but the time devoted to biochemical etiological investigations should be dramatically shortened so as not to delay initiation of specific treatments for hypercortisolism. Biochemical investigations can even be reduced to serial blood samples only, taken over several hours, for cortisol and ACTH measurements to confirm ACTH-dependent Cushing syndrome. Performing time-consuming dynamic tests and BIPSS may be incompatible with both the urgency to treat and the general condition of the patient. Because EAS is the most prevalent etiology in this scenario, we suggest rapidly performing a neck-to-pelvis thin-slice CT, the main priority being to ascertain the absence of an obvious and aggressive ectopic tumor that may require urgent surgical excision and/or antineoplastic medical treatment.[35]

BLA can be performed as a life-saving therapy in critically ill patients. Contemporary studies have reported no deaths, but the rate of perioperative complications may be increased in this situation.[212] Medical treatment using fast-acting steroidogenesis inhibitors, such as ketoconazole and metyrapone, is a valuable alternative, and, given in association at high dosage, ketoconazole and metyrapone have been shown to rapidly and dramatically reduce extremely intense hypercortisolism, giving normalization of UFC within 1 week in 50% of patients.[199] Alternatively, etomidate may be used to rapidly control hypercortisolism in the short term while waiting to perform pituitary surgery or implement other therapeutic alternatives.

Cyclic Cushing Syndrome

A small subset of patients with Cushing disease show alternating periods of normal and increased cortisol secretion. Several terms have been used for this condition, such as “periodic,” “intermittent,” and “cyclical” Cushing syndrome. There is no universal definition for this condition, but demonstration of three peaks and two troughs of cortisol production is usually accepted, with the term “cyclical” being more specifically used when alternating of episodes occurs at a steady rhythm.[213,214] The duration of phases is extremely variable and ranges from days to months. The pathophysiology of this condition, which may occur in all causes of Cushing syndrome, remains unknown.

From a clinical perspective, the clinical course of patients may be unchanged, usually with mild Cushingoïd symptoms, or it may parallel the cortisol production, with episodes of exacerbation and spontaneous improvement or resolution of clinical features such as hypertension, edema, hyperglycemia, and psychiatric symptoms.

The main drawback of this condition is that it may be responsible for aberrant results on standard diagnostic tests, such as normal UFC and normal response to dexamethasone suppression, and thus for an incorrect diagnosis of an absence of Cushing syndrome.[213,214] Biochemical investigations used for the biochemical etiology, including BIPSS, can also lead to erroneous results and should be performed only during a sustained period of hypercortisolism.

Intermittent Cushing disease should be suspected if patients report spontaneous and huge variations in the intensity of clinical symptoms or when clinical symptoms contrast with normal biochemical evaluations. In the latter instance, the possibility of factitious Cushing syndrome because of surreptitious intake of exogenous glucocorticoids should also be ruled out. There is no ideal investigation to diagnose intermittent Cushing disease aside from regular clinical follow-up of patients and repetition of biochemical investigations to identify phases of cortisol hypersecretion.[65] Because of the convenience of sampling, measurement of salivary cortisol is an accepted tool for this purpose.[65] More recently, the measurement of cortisol in hair samples may be useful in the retrospective identification of intermittent oversecretion.[90]

Aggressive Pituitary Corticotroph Adenomas and Corticotroph Carcinomas

Aggressive pituitary tumors correspond to radiologically-invasive tumor with unusually rapid tumor growth rate, or clinically relevant tumor growth despite optimal standard therapies (surgery, radiotherapy, and conventional medical treatments).[9] Aside from local aggressiveness, some tumors metastasize distantly, either hematogenously or through the spinal fluid. Predictors of aggressiveness include the combination of radiological invasion and the presence of proliferative markers (Ki-67 index ≥3% and mitotic count >2) and immunostaining for p53 at histology, plus young age, as well a tumor subtypes such as silent corticotroph adenomas, Crooke cell adenomas, and Nelson syndrome tumors.[7,9-11] Germline genetic testing should be performed in young patients. Treatment of aggressive corticotroph tumors should be discussed by a multidisciplinary expert team and include repeat surgery, pituitary radiotherapy, and medical treatments. Among these, pasireotide and cabergoline may occasionally show transient efficacy.[9,142] The only chemotherapy with established activity is the alkylating agent temozolomide given at a dosage of 150 to 200 mg/m^2 for 5 consecutive days every 28 days and associated with careful monitoring of hematological parameters and liver function tests. Objective radiological responses should be assessed after three cycles and are observed in no more than 50% of patients. High methylguanine-DNA-methyltransferase expression in tumor tissues may predict lack of response, but there are exceptions. In patients with rapid tumor progression on temozolomide treatment, systemic cytotoxic therapy should be administered, although no specific drug can be recommended at the time of writing[9] (see also Chapter 16).

Pediatric Cushing Disease

Cushing disease rarely occurs in children, with approximately 10% of new cases each year occurring in children. Cushing disease is the most common cause of Cushing syndrome and accounts for between 75% and 80% of cases in children and adolescents. However, before the age of 6 years, adrenal diseases are the most common causes. Cushing disease does not show a female predominance in prepubertal children.[215] Pituitary microadenomas are the most common cause of Cushing disease in children. The vast majority of patients with pediatric Cushing disease do not have causative germline genetic defects. Although somatic mutations in *USP8* occur in pediatric corticotroph adenomas,[216] germline mutations of the *AIP, MEN1, CDKN1B, CABLES1,* and *DICER1* genes, responsible for isolated or syndromic Cushing disease, only account for a small percent of cases.[16,17] However, physical characteristics (including birthmarks) and family history should be closely examined to consider whether genetic testing is appropriate.

Disease onset is often insidious but also has some specific clinical differences from adult disease. The most common presentation is a decreased growth rate leading to growth retardation contrasting with weight gain.[215,217] This auxological contrast distinguishes Cushing disease from subjects with simple obesity because most simply obese children are tall. Importantly, and in contrast with the decreased growth velocity, children may have advanced skeletal maturation owing to the secretion of adrenal androgens.[218] Excessive exposure to adrenal androgens combined with gonadotrophin deficiency are also responsible for abnormal virilization, with advanced pubic hair and genital growth in boys associated with prepubertal testicular volumes, or with pubic hair growth in girls showing prepubertal breast development. Easy bruising and muscle weakness may be less common in pediatric patients.[215,217] Psychiatric and cognitive changes can also affect school performance in children.[215,217,219]

The diagnostic algorithm and use of biochemical tools to diagnose Cushing disease is similar to those for adults, but with an emphasis in children on measuring LNSC, taking advantage of its convenience.[215] In children, UFC should be corrected for body surface area (× 1.72 m^2), and in children weighing less than 40 kg the dexamethasone dose is adjusted to 30 μg/kg/day for the 2-day LDDST.[217] Pituitary MRI is as effective in children as it is in adults and, regardless of the methodology used, is positive in only 50% to 60% of cases.[215,220] Given the extreme rarity of EAS in children,[102] the need for BIPSS in ACTH-dependent Cushing syndrome is questionable, especially in children with a clear-cut response to the CRH test.

Transsphenoidal surgery remains the treatment of choice, with roughly similar rates of remission as adults in expert hands.[215]

Recurrences following remission may occur, as in adults, despite postoperative corticotroph insufficiency.[215,221] Conventional radiotherapy used in the setting of failure of pituitary surgery may perform faster than in adults, with reported remission rates as high as 70% within 18 months.[215,219,222] Large pediatric studies looking at the most recent radiosurgery are not currently available; however, proton beam therapy may be considered owing to its ability to limit irradiation of surrounding brain areas. Similarly, until recently there were no medications approved by the US Food and Drug Administration for use in pediatric Cushing disease, leading to off-label prescription of commonly used drugs such as steroidogenesis inhibitors or cabergoline.[142,184] Adrenalectomy is also an option in refractory Cushing disease[219] and, in the opinion of these authors, may ensure better control of hypercortisolism than medical therapy for improving linear growth velocity. Following pituitary surgery, with or without radiotherapy, the incidence of GH deficiency, at least in the short term, is high and prompt evaluation and treatment with human GH is strongly encouraged to ensure growth acceleration and to catch up growth.[215,219] However, despite this, most children do not reach their target height. Pubertal development may also be disturbed owing to the suppressive effect of hypercortisolemia on gonadotropins. Sex steroid replacement should be performed with caution in prepubertal children in order not to compromise final height because of advanced skeletal maturation.[218] Abnormal body composition and fat mass,[223] hypertension,[224] and cardiovascular remodeling may also persist after cure, and management of these is mandatory. Significant psychopathology may persist after remission, and some children may experience a decline in cognitive and school performance 1 year after surgical cure, without associated psychopathology. Residual impairment in quality of life with persistence of forgetfulness, unclear thinking, decreased attention span, and suicide ideation have also been described.[225-227]

Cushing Disease and Pregnancy

Pregnancy rarely occurs in women with Cushing disease owing to dysovulation secondary to cortisol excess. As of 2020, fewer than 300 cases had been published. Causes of Cushing syndrome in pregnancy contrast with those in nonpregnant women. In a review of 122 pregnant women, adrenal causes (mainly adenomas but also carcinomas) represented 62% of cases, and only 35% of women had Cushing disease.[228]

Cushing syndrome during pregnancy is responsible for both maternal and fetal morbidity. The most commonly reported maternal morbidities are hypertension (40%–68%), diabetes or glucose intolerance (25%–37%), and preeclampsia (14%–27%). Maternal death occurred in 2% of cases. The most frequent fetal morbidities were prematurity (43%–66%), intrauterine growth retardation (15%–21%), and spontaneous abortion, intrauterine death, and stillbirth (11%–30%).[228,229]

The diagnosis of Cushing disease during pregnancy is challenging. From a clinical perspective, faciotruncal weight gain, purple striae, diabetes, and hypertension are frequently attributed to the context of pregnancy. The more specific signs of hypercatabolism (bruising, amyotrophia) are rarer. Preeclampsia or intrauterine growth retardation may reveal the disease. From an endocrine perspective, pregnancy is a physiological state of hypercortisolism because of an activation of the HPA axis that is secondary to a progressive increase of CRH and corticotropin secretion by the placenta.[229] The result is a rise in serum, salivary, and urinary cortisol levels that becomes more significant as pregnancy advances. Accordingly, mean serum cortisol levels and 24-hour UFC (measured by LC-MS/MS) in the first, second, and third trimesters of pregnancy were multiplied by 1.7, 2.4, and 3.1, respectively.[230] Nonetheless, a UFC greater than three to four times the ULN should be considered abnormal. In addition, high levels of estrogens increase the synthesis of CBG and cause an overestimation of serum cortisol. The suppression of cortisol following the 1-mg DST is attenuated compared with nonpregnant women, but few data are available concerning the LDDST.[228,229] Serum free cortisol also increases because of pregnancy-induced HPA activation. Cortisol secretion, however, maintains a circadian rhythm despite higher serum levels; measurement of LNSC can therefore be recommended for diagnosis using appropriate thresholds according to the stage of pregnancy.[230,231]

Among other biochemical changes observed during pregnancy, ACTH levels may be less discriminant and may not be suppressed in women with cortisol-secreting adrenal adenomas, possibly owing to pituitary ACTH stimulation by placental CRH or by placental ACTH itself.[229] Consequently, when plasma ACTH concentration is ambiguous with regard to the ACTH-dependency of the disease, it is safe to first perform adrenal imaging by ultrasound to rule out the presence of an adenoma or carcinoma. In ACTH-dependent cases, the performance of dynamic tests (such as the HDDST, CRH, and desmopressin tests) during pregnancy is not precisely known, but ectopic ACTH syndrome is extremely rare (<5% of cases).[228,229] Pituitary MRI without gadolinium injection should be performed, especially if surgery is planned before birth. Bilateral inferior petrosal sinus sampling has been performed in only a few pregnant women with suspected Cushing disease.[229]

Cases of mild and moderate Cushing disease discovered at the end of pregnancy can be managed conservatively by medical treatment of comorbidities. In other cases, pituitary surgery remains the first-line treatment option and should ideally be performed during weeks 12 to 30 of gestation to ensure a minimal rate of maternal and fetal morbidity.[228,229] Radiotherapy is not indicated during pregnancy due both to the delayed results and the potential teratogenicity. Medical therapy, usually initiated during the second or third trimester, is generally a second-line treatment option after surgery. Mitotane is contraindicated during gestation. During pregnancy, metyrapone has been the mostly frequently used medical option.[229] Caution should be exercised with regard to the consequences of the increase in the cortisol precursor 11-deoxycorticosterone, which may worsen hypertension. Rare cases treated successfully with cabergoline at doses of 2.0 to 3.5 mg/week have also been reported, and ketoconazole has been occasionally used with good results, despite its antiandrogenic effect and potential teratogenicity.[229]

Cushing Disease and Chronic Renal Failure

Cushing syndrome has only rarely been described in the setting of chronic renal failure. However, biochemical diagnosis of Cushing syndrome may be difficult for several reasons. Modifications of the serum matrix may be responsible for spuriously increased serum cortisol levels, making it compulsory to use immunoassays using an organic extraction procedure. Decreased glomerular filtration rates result in decreased cortisol excretion, and UFC may be normal despite excessive cortisol production.[68] Chronic renal failure may also activate the HPA axis because of the high inflammatory state and stress of dialysis.[232,233] Consequently, ACTH levels are increased, and, despite the persistence of a normal circadian rhythm of cortisol secretion, LNSC may be increased above normal levels.[232,234] Patients also have abnormal suppression of cortisol after the 1-mg DST.[233,234] This may result from poor dexamethasone absorption, some degree of glucocorticoid resistance, and the chronic inflammatory state. The optimal approach in patients with clinical suspicion includes LDDST and measurement of LNSC because adequate suppression and normal LNSC levels exclude the diagnosis. However, elevated LNSC and abnormal dexamethasone suppression must be viewed with caution. Secondary diagnostic tests for Cushing disease, such as the desmopressin stimulation test, have not been extensively studied in patients with chronic renal failure.

FUTURE DIRECTIONS

Research aims and future expected improvements include:

- Decreasing the latency to diagnosis to reduce the long-term burden of disease.[24]
- Defining efficient and cost-effective algorithms for differential diagnosis, taking into account the pretest probability of Cushing disease and using modern diagnostic tools.[122]
- Improving imaging techniques for the visualization of corticotroph adenomas.[119,123,124]
- Evaluating whether presurgical medical treatment improves surgical outcomes and how long it should be prescribed for.[140]
- Evaluating the utility of venous thromboembolism prophylaxis before and after remission.[42]
- Identifying the best follow-up strategy to diagnose early recurrence at the individual level following successful pituitary surgery.
- Identifying quantitative biological markers of tissular exposure to cortisol to accurately monitor medical therapy doses.
- Evaluating new medical therapies in development and comparing the long-term impact of medical therapies versus bilateral adrenalectomy in patients with surgical failure.
- Defining efficient therapeutic approaches to improve cognitive defects and decreased quality of life in patients with a history of Cushing disease.
- Improving our understanding of the pathophysiology and the classification of corticotroph tumors with multiomics analysis to better anticipate the behavior of individual tumors and identify targeted medical treatments when surgery fails.

TYPES OF CLINICALLY NONFUNCTIONING SELLAR MASSES

Many types of lesions can present as masses in the region of the sella turcica (Table 8.1). The most common are pituitary adenomas. Other lesions include nonpituitary benign tumors, malignant tumors, hyperplasia of any anterior pituitary cell type, different kinds of hypophysitis, cysts, and infiltrative diseases.

Pituitary Adenomas

Nomenclature—Tumors that arise from cells of the anterior pituitary gland that do not metastasize have been called adenomas. The large size and aggressive behavior of some of these tumors has led to the suggestion that the term adenoma be replaced by the term pituitary neuroendocrine tumor.[1]

Classification of Pituitary Adenomas—Adenomas can arise from any normal anterior pituitary cell type: lactotroph, somatotroph, corticotroph, gonadotroph, and thyrotroph. Any pituitary adenoma type may first be recognized as a sellar mass that is apparently nonfunctioning clinically, even those whose hormonal secretion usually causes a recognizable clinical syndrome, such as corticotroph or somatotroph adenomas. In some situations the clinical syndrome (e.g., Cushing syndrome or acromegaly) is present but not recognized; in other situations, the clinical syndrome is relatively subtle or nonexistent. The latter have been referred to as “silent” adenomas.[2] It is probably more accurate, however, to regard the clinical presentations of these adenomas as a spectrum from clinically obvious (e.g., frank acromegaly), to clinically subtle (e.g., slight increase in ring size but still overall normal appearance), to clinically silent (e.g., no clinical manifestations but high levels of insulin-like growth factor 1 (IGF-1)),[3] to totally silent (e.g., no clinical manifestations and a normal IGF-1 level, but immunostaining of excised tissue for growth hormone) (Table 8.2). Corticotroph adenomas exhibit a similar spectrum.[4]

KEY POINTS

- Gonadotroph adenomas are the most common clinically nonfunctioning pituitary adenoma, but corticotroph and somatotroph adenomas may also be clinically nonfunctioning.

The most common pituitary adenoma that presents as a sellar mass is a gonadotroph adenoma. They comprise 40% to 50% of all macroadenomas and approximately 80% of clinically nonfunctioning adenomas. They are often not recognized as being of gonadotroph cell origin, as they secrete inefficiently, and what they do secrete—intact gonadotropins and their subunits—often does not produce a recognizable clinical syndrome. Consequently, these adenomas are often not recognized until they become so large that they cause neurologic symptoms, or they are recognized incidentally when imaging is performed for an unrelated symptom. Occasionally, however, they do cause recognizable clinical syndromes, as described later under “Clinical Syndromes,” and more often they are recognized by finding abnormal serum concentrations of gonadotropins and their subunits.

Etiology of Pituitary Adenomas

All pituitary adenomas appear to be true neoplasms, arising from a somatic mutation of a single progenitor cell that divides repetitively. The evidence comes from studies that show that virtually all pituitary adenomas are monoclonal, that is, arise from a somatic mutation of a single cell.[5,6]

Mutations of specific genes have been identified in association with hereditary pituitary adenomas that are part of clinical syndromes. In multiple endocrine neoplasia type I (MEN1), a mutation of the *MEN1*

TABLE 8.1 Types of Sellar Masses

- Pituitary Adenomas
  - Gonadotroph
  - Corticotroph
  - Somatotroph
  - Lactotroph
  - Thyrotroph
- Other Benign Tumors
  - Craniopharyngioma
  - Meningioma
  - Pituicytoma
- Malignant Tumors
  - Germ Cell Tumor (Ectopic Pinealoma)
  - Chordoma
  - Lymphoma
  - Metastatic Disease
  - Pituitary Carcinoma
- Pituitary Hyperplasia
  - Lactotroph Hyperplasia of Pregnancy
  - Thyrotroph Hyperplasia owing to Primary Hypothyroidism
  - Gonadotroph Hyperplasia owing to Primary Hypogonadism
- Hypophysitis
  - Lymphocytic
  - Anticytotoxic T Lymphocyte–Associated Antigen Immunotherapy
  - IgG4 (Plasma Cell)
  - Granulomatous
- Other
  - Cysts (Rathke's Cleft, Arachnoid, Dermoid, Epidermoid)
  - Infiltrative and Granulomatous Diseases (Sarcoidosis, Langerhans Cell Histiocytosis, Tuberculoma)
  - Abscess
  - Vascular Abnormalities (Aneurysm, Arteriovenous Fistula)

gene[7] results in decreased expression of the tumor suppressor protein menin and development of adenomas of the pituitary, parathyroids, and pancreas. All pituitary adenoma types can occur in MEN1, most commonly lactotroph and somatotroph adenomas, but gonadotroph adenomas[8,9] and those identified only as clinically nonfunctioning[10,11] have also been reported. Another clinical syndrome, the Carney complex,[12] which often results from germline-inactivating mutations in the gene encoding the regulatory subunit type I of the cyclic adenosine monophosphate (cAMP)-dependent protein kinase A, is associated with somatotroph adenomas but not gonadotroph or other clinically nonfunctioning adenomas.

Pituitary adenomas that are familial but not associated with syndromes are referred to as familial isolated pituitary adenomas (FIPAs).[13] These comprise only about 2% of all patients who have pituitary adenomas. Within some families, the adenomas are of the same type in all family members, and within other families, different family members have different adenomas. Somatotroph and lactotroph adenomas are the most common, but clinically nonfunctioning and gonadotroph adenomas may occur. Most are macroadenomas.

Of FIPAs, 10% to 20% are associated with germline mutations of the aryl hydrocarbon receptor-interacting protein (*AIP*) gene.[13,14] Clinical characteristics more likely to predict an *AIP* mutation include age younger than 18 years and growth hormone hypersecretion leading to gigantism.[14] Screening for the *AIP* mutation in family members of patients with known *AIP* mutations allows detection of previously unrecognized adenomas when they are smaller and therefore less likely to have extended outside of the sella[15] (see also Chapter 14).

TABLE 8.2 Spectrum of Functionality of Pituitary Adenomas

Term	Description
Clinically obvious	Typical physical features of excessive hormonal hypersecretion (e.g., classical acromegaly or Cushing syndrome)
Clinically subtle	Subtle physical features of excessive hormonal hypersecretion (e.g., subtle acromegaly or Cushing syndrome)
Clinically silent	Elevated serum concentration of pituitary hormone (follicle-stimulating hormone, insulin-like growth factor 1, adrenocorticotropic hormone) but not even subtle clinical manifestations
Totally silent	Type of adenoma identifiable only by immunostaining of excised adenoma; normal serum concentration of hormone typically secreted by that cell type

Genetic mutations associated with the development of most isolated pituitary adenomas are not known, but approximately 40% of somatotroph adenomas are associated with mutations of the gene encoding the alpha-subunit of the G stimulatory protein ($G_{s\alpha}$) and, as a consequence, constitutively activate adenylyl cyclase and increase cAMP, which is mitogenic to somatotroph cells, thereby resulting in somatotroph adenomas.[16]

Other Benign Tumors

Craniopharyngiomas. Craniopharyngiomas are solid or mixed solid-cystic epithelial tumors that arise from remnants of Rathke's pouch, either within or above the sella.[17] Two distinct types can be identified: adamantinomatous, which occur either in childhood or adulthood; and papillary, which occur only in adulthood. Adamantinomatous craniopharyngiomas have activating mutations of *CTNNB1*, the gene that encodes β-catenin, and an activated Wnt signalling pathway.[18] Papillary craniopharyngiomas have mutations in the *BRAF* oncogene.[18]

The major presenting symptoms are growth retardation in children and abnormal vision in adults. Hormonal abnormalities are also common, including hyperprolactinemia, deficiencies of anterior pituitary hormones, and diabetes insipidus. Magnetic resonance imaging (MRI) often reveals a heterogeneous signal, and computed tomography (CT) scan often shows calcifications.

Demonstration of the molecular abnormality associated with each type of craniopharyngioma offers the potential of targeted medical treatment.[19] Administration of BRAF inhibitors has already been reported to achieve clinical responses in cases of papillary tumors (see also Chapter 11, where these tumors and related parasellar masses are discussed in more detail).

Meningiomas. These are usually benign and arise from the meninges anywhere within the head. About 20% arise near the sella, causing visual impairment and hormonal deficiencies. By MRI, meningiomas typically emit a low signal on T1-weighted images and a high signal on T2-weighted images and exhibit intense enhancement after gadolinium and a "dural tail," a thickening of the dura adjacent to the meningioma that tapers.

Pituicytomas. Pituicytomas are rare, benign tumors that arise from pituicytes,[26] which are glial cells of the posterior pituitary. They have no hormonal secretory function and can be diagnosed only by the characteristic histologic pattern of elongated cells in bundles and immunostaining for thyroid transcription factor 1.[20]

Malignant Tumors

Some malignant tumors arise within or near the sella, and others metastasize there. Malignancies that arise in the parasellar region include germ cell tumors, sarcomas, chordomas, lymphomas, and pituitary carcinomas.

Germ Cell Tumors (Ectopic Pinealomas). Suprasellar germ cell tumors usually occur through the third decade of life and are histologically and biologically similar to other germ cell tumors, such as germinomas, teratomas, embryonal carcinomas, and choriocarcinomas. They may present with headaches, nausea, vomiting, lethargy (from increased intracranial pressure with pineal lesions), diplopia, paralysis of upward conjugate gaze, hypopituitarism, and diabetes insipidus. If the tumor is in the pineal, imaging will show a mass in the third ventricle; if the tumor is in the infundibulum, it will be thickened. Serum concentrations of human chorionic gonadotropin beta and/or alpha fetoprotein may be increased. Although these lesions are highly malignant and metastasize readily, they are also highly radiosensitive.

Chordomas. Chordomas are slowly growing malignancies that arise from notochord remnants. Chordomas that arise in the clivus, the bone that is the base of the sella turcica, and may present with headaches, visual impairment, and anterior pituitary hormonal deficiencies. MRI often shows a heterogeneous sellar mass associated with osteolytic bony erosion and calcification that may be distinct from the normal pituitary. Histologically, they exhibit markers for epithelial cells, including cytokeratin and vimentin. After surgical excision, local invasion and recurrence commonly occur; mean patient survival is about 5 years. Rarely, they become sarcomatous. A less aggressive subtype is the chondrosarcoma.

Primary Lymphoma. Primary central nervous system lymphoma sometimes involves the pituitary and hypothalamus. A review of 13 patients with primary pituitary lymphoma noted neurologic symptoms, including headaches and visual and oculomotor impairment and/or deficiencies of anterior pituitary hormones and vasopressin.[21] MRI showed a sellar mass with variable extrasellar extension.

Metastatic Disease. Metastases to the hypothalamus and pituitary gland occur most commonly with breast cancer in women and lung cancer in men but are also encountered with other cancers.[22] Symptoms include diabetes insipidus, anterior pituitary dysfunction, visual field defects, retroorbital pain, and ophthalmoplegia. The metastases may be the presenting sign of previously undiscovered malignancy.

Pituitary Carcinoma. Carcinoma arising from anterior pituitary cells is quite rare. When it does occur, the malignancy can arise from any anterior pituitary cell type; lactotroph, somatotroph, corticotroph, thyrotroph, and gonadotroph carcinomas have been reported.[23] Diagnosis is made by finding a distant metastasis (see also Chapter 15).

Pituitary Hyperplasia

Hyperplasia of any anterior pituitary cell type can occur and results in generalized enlargement of the pituitary. The causes are both physiologic and pathologic. During normal pregnancy, increased estradiol secretion causes lactotroph hyperplasia, causing an average increase of about 2.5 mm in each dimension.[24] When a target gland fails, the resulting lack of feedback inhibition on the corresponding pituitary trophic hormone-secreting cells causes hyperplasia. For example, longstanding, untreated primary hypothyroidism causes thyrotroph hyperplasia and symmetrical pituitary enlargement, and treatment with thyroxine reverses the enlargement.[25] Similarly, longstanding, untreated primary hypogonadism causes gonadotroph hyperplasia. A neuroendocrine tumor that secretes growth hormone–releasing hormone causes somatotroph hyperplasia.[26]

Hypophysitis

Several types of hypophysitis have been recognized.[27] Most types are characterized by diffuse enlargement of the pituitary, and often the stalk, that regresses within months of the diagnosis, as well as hypopituitarism that is likely to be permanent. In some series, hypoadrenalism is the most common hormonal deficiency, but in other series other hormonal deficiencies are more common.[28]

One type of hypophysitis is lymphocytic, which sometimes occurs in late pregnancy or postpartum but can also be seen in women who are not pregnant, as well as infrequently in men.[29] It is characterized by headaches whose intensity is out of proportion to the size of the lesion. Another type is caused by immune checkpoint inhibitors, especially ipilimumab, used to treat malignant melanoma and other malignancies.[30] Hypophysitis also occurs because of infiltration of plasma cells, which produce immunoglobulin G4 (IgG4). This type may occur in association with IgG4 inflammation of other organs, most notably the pancreas, causing pancreatitis. Although this condition is not common, it was detected by screening in seven of 170 consecutive patients with hypopituitarism.[31] Granulomatous hypophysitis has been reported in association with systemic granulomatous conditions, such as Wegener granulomatosis (also known as "granulomatosis with polyangiitis") and tuberculosis.

Other Sellar Masses

Rathke's Cleft and Other Cysts. Remnants of the embryonic Rathke's pouch that persist may enlarge during adulthood and present as a sellar mass. These may present with neurologic findings, such as headaches and visual disturbances, or with endocrinologic abnormalities, such as hyperprolactinemia, hypopituitarism, and diabetes insipidus. The majority of Rathke's cleft cysts, however, are small and do not increase in size during observation.[32,33] Other sellar cysts include arachnoid, epidermoid, and dermoid cysts.

Infiltrative and Granulomatous Diseases. Infiltrative diseases, such as sarcoidosis[34] and Langerhans cell histiocytosis,[35] may cause a sellar or hypothalamic mass and/or widening of the pituitary stalk. Tuberculomas of the sellar region may occur as part of systemic infection or may be isolated. Because these lesions primarily affect the hypothalamus and infundibulum, diabetes insipidus is common, whereas anterior pituitary hormone deficiencies are less frequent. Infiltrative sarcoidosis of this area occurs in most patients with central nervous system sarcoid involvement.[38] Typically these patients present with varying degrees of anterior pituitary failure, with or without diabetes insipidus.

Abscess. Pituitary abscesses, which are rare, can occur in a normal or diseased pituitary gland. In immunocompromised subjects, they may be caused by fungi (*Aspergillus, Nocardia,* or *Candida albicans*) or *Pneumocystis carinii.* In a series of 24 patients, 16 presented with symptoms and physical findings consistent with a pituitary mass, whereas only eight had features suggestive of infection, such as fever, leukocytosis, or meningismus.[36] MRI is usually unable to distinguish between pituitary abscess and pituitary adenoma, so most patients are diagnosed at the time of surgical exploration.

Vascular Abnormalities. Aneurysms and arteriovenous fistulas can present as sellar masses. Because they arise from the cavernous sinus, they may cause cranial nerve palsies, eye pain, and headaches. They can usually be recognized by MRI, but a highly vascular meningioma may be confused with an aneurysm. CT or magnetic resonance angiography is essential when these are suspected to avoid inappropriate—and dangerous—surgery.

CLINICAL PRESENTATIONS

Clinically nonfunctioning sellar masses, by definition, do not cause florid syndromes of hormonal excess, and as a result often grow unrecognized until they become so large as to cause neurologic symptoms or symptoms of hormonal deficiencies. An equally common presentation is as an incidental finding when imaging is performed for an unrelated reason, such as head trauma. Least common is hormonal hypersecretion by a pituitary adenoma, although not associated with an obvious clinical syndrome. These may be called clinically subtle if there are mild clinical manifestations, or clinically silent if there are no clinical manifestations at all but the adenoma can be recognized biochemically (Table 8.2). Hormonal hyposecretion is common, but usually not the presenting manifestation. Pituitary apoplexy is a rare presentation.

KEY POINTS

- Clinically nonfunctioning pituitary adenomas are as likely to come to medical attention as an incidental finding as a manifestation of the adenoma.

Neurologic Presentations

Visual Abnormalities. A mass within or near the sella that stretches the optic chiasm or nerves sufficiently may result in visual impairment. Masses that arise below the optic chiasm, such as pituitary adenomas, may extend superiorly and elevate and then stretch the chiasm sufficiently to cause visual field abnormalities, initially of the upper, outer quadrants (bilateral superior quadrantinopia) and then of the outer halves (bilateral hemianopia), before much later affecting central vision and visual acuity. Masses that arise above the chiasm may first cause asymmetric impairment of inferior visual fields. They may be reversible once the masses have been partially or completely excised.

Oculomotor Abnormalities. Masses that arise within the sella and extend into a cavernous sinus may affect one or more of the oculomotor nerves on that side, resulting in diplopia, impaired extraoculomotor movements, and/or ptosis.

Other. Other neurologic manifestations of sellar masses are headaches, cerebrospinal fluid leakage and meningitis, and hydrocephalus. Any kind of sellar mass can cause a headache; those that grow more rapidly are more likely to do so. Cerebrospinal fluid (CSF) rhinorrhea is uncommon. When it does occur, it is the result of an aggressive pituitary adenoma that extends inferiorly and erodes the cribriform plate, allowing leakage of CSF, which in turn predisposes to retrograde infection and meningitis. Hydrocephalus is also uncommon. When it occurs it is often the result of a suprasellar lesion that obstructs the fourth ventricle.

Incidental Finding

As a result of the ready availability of imaging techniques in developed countries, sellar masses are often discovered when imaging is performed for an unrelated reason. Although many lesions discovered in this manner are small, others are larger than 1 cm in diameter, and some are even associated with hormonal hyper- and hyposecretion and with neurologic abnormalities that had not been previously recognized. In a prospective study of 269 patients referred for evaluation of a pituitary adenoma, the adenoma was detected incidentally in 131 (48.7%), of which 111 were macroadenomas (Table 8.3).[37] The reasons for the imaging were legion; the most common were head trauma and neurologic and ear symptoms.

TABLE 8.3 Presentations of 269 Clinically Nonfunctioning Pituitary Adenomas

- Incidental Finding ($n = 131$)
  - Head and neck symptoms
  - Eye symptoms
  - Neurologic symptoms

TABLE 8.4 Hormonal Criteria for the Diagnosis of Gonadotroph Adenomas

Men	Women
Supranormal Basal Serum Concentrations of	
FSH	FSH but not LH
α LHβ, or FSHβ subunits	Any subunit relative to intact FSH and intact LH
LH and testosterone	FSH and estradiol (in premenopausal women)
Supranormal Response to TRH of	
FSH	FSH
LH	LH
LHβ (most common)	LHβ (most common)

FSH, Follicle-stimulating hormone; *LH*, luteinizing hormone; *TRH*, thyrotropin-releasing hormone.

Endocrinologic Presentations

Hormonal Excess: Gonadotroph Adenomas

Serum Concentrations of Gonadotropins and Their Subunits. Although gonadotroph adenomas are typically nonfunctioning clinically because they secrete inefficiently and because their secretory products—intact gonadotropins and their subunits—usually do not cause a clinical syndrome, they often can be identified by their basal and stimulated secretory products (Table 8.4). Gonadotroph adenomas often secrete sufficient intact follicle-stimulating hormone (FSH) to result in a supranormal serum FSH concentration from minimal to ten times the upper limit of normal.[38] In contrast, gonadotroph adenomas rarely produce supranormal serum concentrations of intact luteinizing hormone (LH), but when they do, the serum testosterone concentration is elevated.[39] A small percentage of patients who have gonadotroph adenomas have supranormal basal serum concentrations of the common α-subunit.[38] Administration of synthetic thyrotropin-releasing hormone (TRH) to patients who have gonadotroph adenomas often produces an increase in the serum concentrations of intact gonadotropins and their subunits, especially of the LHβ subunit.[38]

KEY POINTS

- A gonadotroph adenoma can often be recognized *in vivo* by a supranormal concentration of follicle-stimulating hormone.

Clinical Syndromes. Although gonadotroph adenomas usually do not result in recognizable clinical syndromes, uncommonly they may cause menstrual irregularities and ovarian hyperstimulation in premenopausal women, testicular enlargement in men, and precocious puberty in children. They are also subject to apoplexy when synthetic TRH is administered for diagnosis or synthetic gonadotropin-releasing hormone (GnRH) or a GnRH analog is administered for treatment[40] (Table 8.5).

Menstrual irregularities and ovarian hyperstimulation result from continuous secretion of intact FSH in a premenopausal woman.[40,41] Continuous secretion of FSH, in contrast to cyclical secretion by normal gonadotroph cells, results in continuous stimulation of the ovaries, with the result that the ovaries become very large because of multiple, large cysts. Continuous stimulation of the ovaries also results in continuous secretion of estradiol, so ovulation does not occur. The resulting clinical presentation is usually oligomenorrhea and infertility. Pelvic ultrasound shows multiple large cysts and a widened endometrial "stripe" (Fig. 8.1). These patients typically have elevated serum FSH, suppressed LH, and elevated α-subunit and estradiol.[40]

TABLE 8.5 Clinical Syndromes Associated With Gonadotroph Adenomas

Ovarian hyperstimulation
Pituitary apoplexy following administration of thyrotropin-releasing hormone, gonadotropin-releasing hormone, or a gonadotropin-releasing hormone analog
Large testicular size
Premature puberty in a prepubertal boy

The estradiol concentration is often higher than 500 pg/mL and sometimes as high as 2000 pg/mL. The clinical picture of oligomenorrhea and multiple ovarian cysts can be mistaken for polycystic ovarian syndrome, but administration of a superactive GnRH analog to a patient with a gonadotroph adenoma results in increased, rather than decreased, FSH secretion and ovarian size and function.[42] Excision of the gonadotroph adenoma can lead to restoration of normal gonadotropin secretion, ovarian function, and pregnancy.[42]

Other clinical presentations of gonadotroph adenomas are even less common (Table 8.5). In men, testicular size may be large.[39,40,43] In boys and girls, isosexual precocity may occur.[40] Administration of TRH diagnostically or a GnRH analog therapeutically, such as to treat prostate cancer, in a patient with a previously unrecognized gonadotroph adenoma can cause pituitary apoplexy.[44]

Hormonal Excess: Other Pituitary Adenomas. Although somatotroph and corticotroph adenomas often secrete efficiently and therefore often result in the classic clinical syndromes of acromegaly and Cushing syndrome, some somatotroph and corticotroph adenomas secrete growth hormone and adrenocorticotropic hormone (ACTH) excessively but do not cause the corresponding clinical syndrome classically or even subtly. These can be called silent adenomas (Table 8.2). Somatotroph adenomas that cause an elevated serum concentration of IGF-1 but not even subtle features of acromegaly can be termed clinically silent, and those that do not elevate IGF-1 can be called totally silent.[3] Similarly, corticotroph adenomas that cause an elevated plasma ACTH concentration and/or elevated urine cortisol excretion can be termed clinically silent, and those that cause neither hormonal abnormality can be called totally silent.[4] In a retrospective study of 100 consecutive surgically-excised pituitary macroadenomas, 24 were somatotroph adenomas, and, of these, eight were clinically silent.[3] In a prospective study of 124 patients with pituitary macroadenomas, 20 were corticotroph adenomas.[4] Of these, eight were clinically silent, and five were totally silent.

Hormonal Deficiencies. The large size of many sellar masses commonly causes hormonal hyposecretion because of compression of the pituitary or stalk, but these deficiencies often do not prompt the patient to seek medical attention. In the prospective study of clinically nonfunctioning pituitary adenomas described above, of the 131 patients

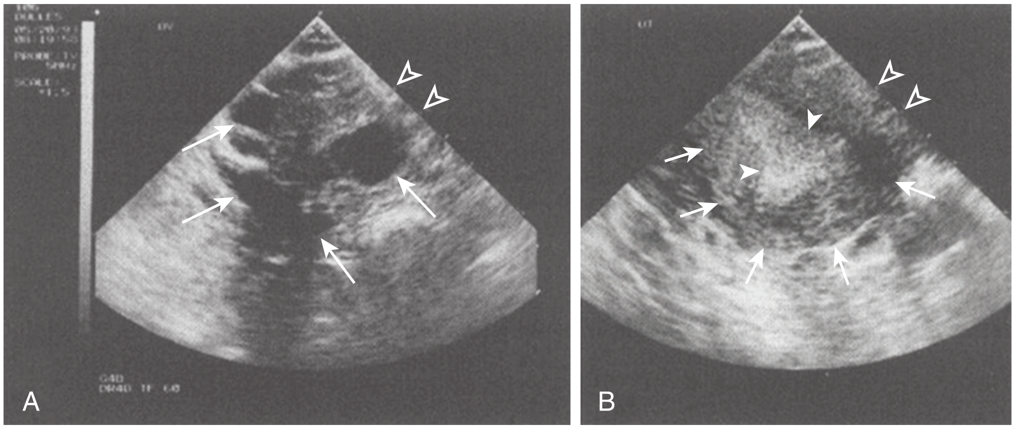

Fig. 8.1 Ultrasound of **A**, ovaries and **B**, uterus in a 39-year-old woman who had a gonadotroph adenoma secreting follicle-stimulating hormone and causing ovarian hyperstimulation. In **A**, the *closed arrowheads* indicate large ovarian cysts. In **B**, the *arrows* indicate the uterus, and the *closed arrowheads* indicate the thickened endometrium. The distance between the *open arrowheads* is 1 cm. (From Djerassi A, Coutifaris C, West VA, et al. Gonadotroph adenoma in a premenopausal woman secreting follicle-stimulating hormone and causing ovarian hyperstimulation. *J Clin Endocrinol Metab*. 1995;80:591-594.)

whose adenomas were detected incidentally, 30 were hypogonadal, 13 hypothyroid, and nine hypoadrenal.[37]

Pituitary Apoplexy

Sudden bleeding into and infarction of the pituitary, called pituitary apoplexy, is a dramatic presentation of an adenoma.[45] It is an uncommon event; its incidence in one study was 0.17 episodes/100,000 persons per year.[46] It may occur in patients known to have an adenoma, but it may be the event that brings the adenoma to medical attention. Precipitating factors include initiation of anticoagulant treatment and administration of TRH diagnostically and a GnRH analog therapeutically.[45] The most common symptom is the sudden onset of severe headache. Visual symptoms include oculomotor palsies because of sudden expansion of the pituitary into a cavernous sinus and visual field deficits because of elevation of the optic chiasm. Hypopituitarism is common, including the sudden onset of cortisol deficiency, which may be life-threatening if not recognized and treated immediately.

DIAGNOSIS

Establishing the diagnosis of a clinically silent sellar mass may proceed from recognizing that a patient's visual abnormality or other neurologic symptom could be caused by a sellar lesion, to confirming the presence of the lesion by an imaging procedure, to attempting to characterize the lesion by its hormonal features. If the sellar mass was found incidentally when imaging was performed because of symptoms unrelated to the mass, the next step is to attempt to characterize the lesion by its hormonal features.

Utility of Diagnosing a Clinically Nonfunctioning Sellar Mass

Identifying the specific type of sellar mass is desirable to distinguish a pituitary adenoma from other lesions and, if a pituitary adenoma, to provide a marker by which to monitor the response to treatment. Identifying the lesion as being of pituitary rather than nonpituitary origin is of value because it may influence treatment. If surgery is indicated, for example, the surgical approach to a pituitary adenoma may be different from that for another lesion. If the lesion is a somatotroph adenoma, identified by an elevated serum concentration of IGF-1, medical treatment may be an option. Finding a tumor marker such as elevated IGF-1, characteristic of a somatotroph adenoma, or elevated serum FSH, characteristic of a gonadotroph adenoma, not only identifies the lesion as being of somatotroph or gonadotroph origin but also provides a means by which to follow the response to treatment. For example, when the serum FSH concentration is elevated before surgery, the decrease after surgery correlates with reduction in adenoma mass seen by imaging.[47]

Imaging of the Sellar Region

MRI is the best imaging technique for the sellar region. Pituitary adenomas tend to be relatively symmetrical, although there are notable exceptions. They enhance on T1-weighted images following the administration of gadolinium, although to a lesser degree than normal pituitary tissue (Fig. 8.2). Several MRI features suggest a greater likelihood of a pituitary adenoma or of another type of lesion, but no feature is pathognomonic. A lesion that appears to be entirely cystic, for example, suggests a lesion such as a Rathke's cleft cyst, but occasionally a pituitary adenoma appears entirely cystic by MRI. A sellar mass that is irregular in shape and emits a heterogeneous signal is more likely to be a craniopharyngioma, but a pituitary adenoma can present similarly. A converse example is an invasive lesion of the clivus, which is typical of a chordoma, but some pituitary adenomas extend primarily into the clivus and therefore can be mistaken for a chordoma. Because of the limitations of imaging in distinguishing types of sellar lesions, endocrinologic testing is invariably necessary.

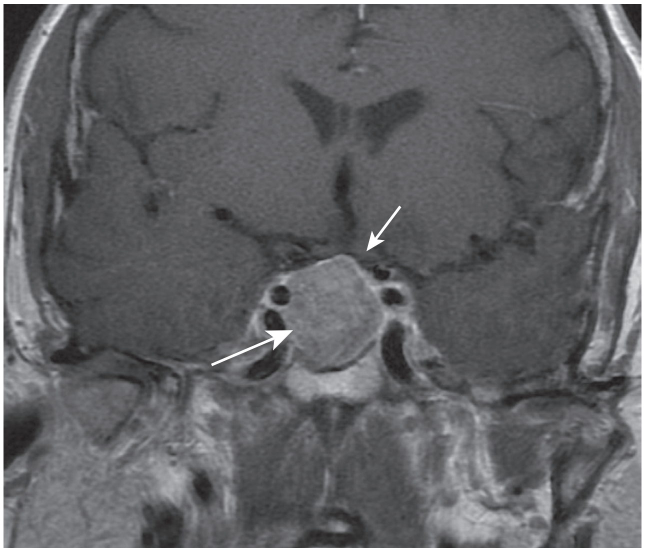

Fig. 8.2 Magnetic resonance image of a sellar mass (*larger arrow*) showing a brighter signal than the surrounding central nervous system tissue after administration of gadolinium. The mass slightly elevates the optic chiasm (*smaller arrow*). The mass was identified as a gonadotroph adenoma when the excised tissue showed strong immunostaining for the transcription factor steroidogenic factor 1 (Fig. 8.3).

Endocrinologic Tests

Sellar mass lesions should be evaluated by measurement of the serum concentrations of pituitary hormones and related target gland hormones to determine if any abnormality suggests that the lesion is a specific type of pituitary adenoma. A prolactin concentration above 100 ng/mL, and especially above 200 ng/mL, suggests a lactotroph adenoma. An elevated IGF-1 concentration suggests a somatotroph adenoma even if the patient does not exhibit clinical features of acromegaly.[3] An elevated plasma ACTH and/or 24-hour urine cortisol suggests a corticotroph adenoma, even if the patient does not exhibit features of hypercortisolemia.[4] An elevated serum T4 associated with a thyroid-stimulating hormone (TSH) concentration that is not suppressed suggests a thyrotroph adenoma (see Chapter 9).

Suspicion that the lesion is a gonadotroph adenoma depends on specific combinations of intact gonadotropins and their subunits (Table 8.4). The combinations differ somewhat in men and women. In a man who has a pituitary macroadenoma, elevated basal serum concentrations of intact gonadotropins and/or their subunits alone or in combination with responses of any of these to TRH is strong evidence that the adenoma is of gonadotroph origin.[38] An elevated basal FSH concentration is common.[38,43] In a woman of postmenopausal age, elevated basal serum concentrations of intact FSH or gonadotropin subunits are usually of little diagnostic value, because either the adenoma or the nonadenomatous postmenopausal gonadotroph cells could be the source. However, a gonadotroph adenoma is likely if intact FSH is markedly elevated but LH is not at all elevated, or if one of the gonadotropin subunits is distinctly elevated but intact FSH and LH are not elevated.[48] In a woman of premenopausal age, ovarian hyperstimulation, including elevated serum estradiol concentration, as discussed earlier, elevated FSH out of proportion to LH levels, or an elevated basal α-subunit concentration all point to the gonadotroph nature of the sellar mass.[40]

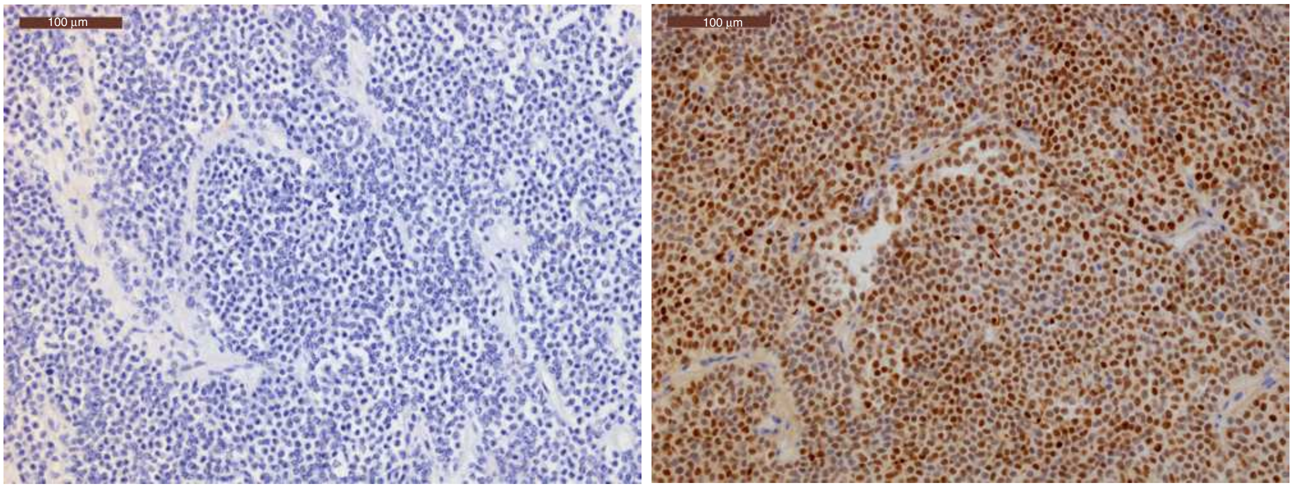

Fig. 8.3 Immunostaining of the excised pituitary adenoma shown by magnetic resonance imaging in Fig. 8.2. Immunostaining for follicle-stimulating hormone β (*left panel*) is negative, but immunostaining for the transcription factor steroidogenic factor 1 (*right panel*) identifies it as a gonadotroph adenoma. Note that the adenoma cells stain uniformly and strongly, but the endothelial cells along the blood vessels do not stain. (Courtesy of MacLean Nasrallah, MD, PhD.)

Gonadotroph adenomas can usually be readily distinguished from pituitary enlargement because of gonadotroph hyperplasia that results from longstanding primary hypogonadism. In primary hypogonadism, the pituitary enlargement is not as prominent, and both gonadotropins are elevated.

Pathologic Evaluation

Even when the identity of a sellar mass cannot be determined *in vivo*, pathologic examination of excised tissue can usually make this determination. By hematoxylin-eosin staining, pituitary adenoma cells do not exhibit the normal pituitary glandular pattern but are arranged in cords or sheets, sometimes interspersed with varying amounts of fibrous tissue. In an adenoma, cells are usually homogeneously similar in size, but cell size varies considerably among adenomas. Immunostaining for pituitary hormones (growth hormone, ACTH, prolactin, FSHβ, LHβ and TSHβ, and α-subunit) often identifies the adenoma type. Most adenomas that do not stain for any pituitary hormones and were previously called "null cell" adenomas can be identified by staining for the transcription factors associated with the differentiation of specific pituitary cell types. Most notably, adenomas previously classified as "null cell" by staining for FSHβ and LHβ can now be identified as gonadotroph adenomas by staining for the transcription factor steroidogenic factor 1 (SF-1) (Fig. 8.3). In a study of 516 consecutive adenomas, 119 could not be identified by hormone immunostaining, but 79 of these could be identified as gonadotroph adenomas by staining for SF-1, 32 as corticotroph adenomas by staining for T-box pituitary restricted transcription factor (T-Pit), and two as being of somatomammotroph lineage by staining for Pit1 (Fig. 8.4).[49]

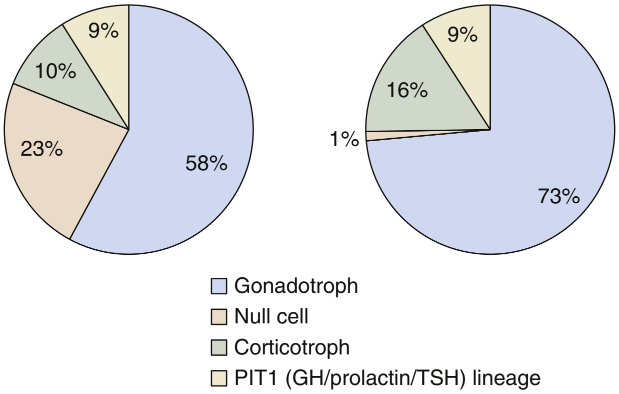

Fig. 8.4 Improved identification of pituitary adenomas by immunostaining for transcription factors compared to staining for pituitary hormones. By immunostaining for pituitary hormones (left), the cell type of 23% of 516 excised pituitary adenomas could not be identified; they were therefore classified as null cell. By immunostaining for pituitary transcription factors (right), the cell type of only 1% could not be identified. *GH,* Growth hormone; *TSH*, thyroid-stimulating hormone. The complementary role of transcription factors in the accurate diagnosis of clinically nonfunctioning pituitary adenomas. *Endocr Pathol.* 2015;26:349-55.)

TREATMENT

When a clinically nonfunctioning sellar mass is not detected until it becomes so large that it causes significant visual impairment, treatment should reduce the size of the mass as soon as possible. Transsphenoidal surgery is the only treatment that meets this criterion. If substantial residual adenoma tissue remains after surgery, radiation is usually effective in preventing regrowth. Several pharmacologic treatments have been tried, but none reduces the size of clinically nonfunctioning adenomas reliably. Observation alone is a satisfactory approach in the absence of neurologic symptoms.

Surgery

Surgical Approaches. Transsphenoidal surgery using an operating microscope was introduced in the 1970s. Since the early 2000s, transsphenoidal surgery using an endoscope has been used increasingly because it affords a wider, more panoramic field of vision, better illumination, and the ability to see around corners. These advantages are particularly helpful in surgery of clinically nonfunctioning pituitary adenomas, which tend to be large and extend beyond the sella.[50] The endoscopic approach also facilitates surgery on large adenomas, because it allows removal of a piece of the clivus for an "extended" approach beyond the sella. Although few studies have compared the two techniques directly, retrospective series and metaanalyses show that the endoscopic technique results in achieving gross total removal more often and in leaving less residual when the adenoma extends beyond the sella.[50]

KEY POINTS

- Transsphenoidal surgery by a very experienced pituitary surgeon has a high likelihood of removing a large amount of a clinically nonfunctioning pituitary adenoma and a low likelihood of serious adverse events.

Efficacy of Surgery. Efficacy of surgery for a clinically nonfunctioning pituitary adenoma can be judged by the amount of the adenoma tissue excised and the amount remaining, the reduction in serum concentrations of secretory products that were elevated before surgery, improvement in vision, and restoration of pituitary function that was subnormal before surgery. Complete resection of adenoma tissue is generally lower the larger the lesion and the degree of extension outside of the sella, especially into the cavernous sinuses. In a prospective, multicenter study of 260 patients with clinically nonfunctioning adenomas with an average diameter of 2.5 cm, gross total resection was achieved in approximately 80% by both the microscopic and endoscopic techniques.[51] Gross total resection was somewhat less, approximately 70%, when the average diameter was greater than 3.0 cm and approximately 40% (by the microscopic technique) or 60% (by the endoscopic technique) when the adenoma extended into a cavernous sinus, as judged by Knosp grades 3 and 4.[51] Vision that was impaired before surgery improves to some extent in the majority of patients following surgery. Visual fields are more likely to improve the younger the patient and the shorter the duration of visual symptoms, as well as in the preoperative absence of central field involvement or abnormal visual acuity.[52-54] Hormonal function that was abnormal before surgery may recover afterwards in a substantial minority of patients.[55-58] The chance of recovery by axis varies among studies. Recovery has been reported as late as a year or more after surgery.[57,58]

Complications of Surgery. Serious complications of transsphenoidal surgery, whether endoscopic or microscopic, include carotid artery injury, central nervous system injury, loss of vision, ophthalmoplegia, CSF leak and meningitis, and death. Other complications include diabetes insipidus, which can be transient or permanent, syndrome of inappropriate antidiuretic hormone secretion (SIADH), and new anterior pituitary hormone deficiencies. Serious side effects are uncommon when the procedures are performed by surgeons who have great experience. In the study comparing the results of endoscopic and microscopic surgery, in which all participating neurosurgeons had great experience in pituitary surgery, each complication occurred in less than 1% of patients in both groups.[51] The incidence of serious complications is greater, however, when surgery is performed by neurosurgeons with less experience. In a survey taken before the endoscopic technique was widely used, neurosurgeons were asked to report their own experience with microscopic surgery.[59] Neurosurgeons who reported performing fewer than 200 total procedures reported approximately five to six times as many serious complications as neurosurgeons who reported performing more than 500 procedures.

Evaluation of the Results of Surgery. The effects of surgery on vasopressin secretion, anterior pituitary function, residual adenoma volume, and visual function should be evaluated. If diabetes insipidus occurs, it usually will be within 24 to 48 hours and may be transient or permanent. Whether or not diabetes insipidus occurs, SIADH may occur approximately 1 week after surgery. It is possible, although not common, for diabetes insipidus shortly after surgery to be followed by SIADH 1 week afterwards, and for that to be followed by permanent diabetes insipidus (see also Chapter 12).

Any hormone that was hypersecreted before surgery, such as FSH, ACTH, or IGF-1, can be used as a marker to judge the extent of removal of the adenoma. The possibility of anterior pituitary hormone deficiencies should be evaluated because deficiencies before surgery can improve afterwards, but surgery can also cause new deficiencies. This testing should be performed first about a month after surgery, but deficiencies before surgery have been reported to improve up to a year or more afterwards.

The anatomic effects of surgery should be evaluated by MRI at least 1 month afterwards. If visual fields were abnormal before surgery, they should be assessed afterwards.

Radiation

Radiation therapy is used primarily to prevent growth of residual adenoma tissue following surgery, especially when a considerable amount of tissue remains and/or the risk of growth appears to be high. In a retrospective study of 132 patients with clinically nonfunctioning pituitary adenomas treated by transsphenoidal surgery and then observed for a mean of 7.6 years afterwards, recurrence occurred in 10.7% of those who had no residual adenoma visible, 38.8% of those who had intrasellar residual adenoma, and 66.7% of those with residual extrasellar extension.[60] Radiation is not commonly used as primary therapy because a decrease in size may take years.

Types of Radiation. Radiation therapy has been used to treat pituitary adenomas for decades. Current techniques employ radiation from one of three sources: high-energy x-rays (photons) from a linear accelerator, gamma radiation from a ^{60}Co source, and protons from a cyclotron. Radiation from all three sources can be administered as a single high dose (18–20 Gy) or in multiple small doses over 5 to 6 weeks for a total dose of 45 to 50 Gy. Single-dose techniques are often referred to as "stereotactic radiosurgery," which is a misnomer as there is no surgery. All of the techniques use computer-generated models based on MRI so that the radiation conforms to boundaries of the lesion.

The most important factors in choosing between a single, high dose and multiple, fractionated low doses are the distance of the lesion from the optic pathways and the size of the adenoma tissue to be radiated. Adenoma tissue that is not at least 3 to 5 mm from the optic pathway should be treated by fractionated radiation to decrease the risk of blindness. Adenomas that are very large, (e.g., >3 cm in diameter), should also be treated by fractionated radiation to reduce the total dose and decrease the risk of blindness. The choice of the radiation source is based on availability.

Efficacy of Radiation (See also Chapter 16). All modalities of radiation therapy currently employed have been shown to be effective in preventing further growth of clinically nonfunctioning pituitary adenomas. The relative efficacy of the different modalities cannot be compared directly, however, because published studies report on a single modality. In series of patients treated with fractionated radiotherapy using a linear accelerator[61,62] or proton beam[63] and observed for a median of 40 months or more, adenoma size was reduced or stable in 90% to 100%. In a review of 25 studies involving 1621 patients, of whom 452 had clinically nonfunctioning pituitary adenomas and were treated with single-dose radiation from a linear accelerator, gamma source, or proton beam, adenoma size was controlled in about 90%

during follow-up of more than 40 months.[64] In a report from a single center at which 100 clinically nonfunctioning adenomas were treated with single-dose radiation from a gamma source and followed for a median of 45 months, adenoma volume decreased or remained stable in 92% of patients.[65]

Complications of Radiation. Although current radiotherapy techniques offer the theoretical advantage of targeting the tumor by stereotactic means, new deficiencies of anterior pituitary hormones and neurologic complications occur following these treatments. In the series of 100 patients with clinically nonfunctioning adenomas treated with single-dose gamma radiation and followed for a median of 45 months, 20% developed new hypopituitarism.[65] In the review of 35 studies involving 1621 patients, optic neuropathy occurred in about 1%, other cranial neuropathies in 1.3%, and parenchymal brain damage in about 0.8%.[64]

Management of Patients After Radiation. Hormonal evaluation, both for excessive secretion of the hormones that were secreted excessively by the adenoma before treatment and for anterior pituitary hormone deficiencies, should be performed 6 and 12 months after radiation and once a year thereafter. Evaluation of adenoma size by MRI should be performed 1 year after radiation; and if the mass is smaller, less frequently thereafter. Neuroophthalmologic evaluation should be repeated after radiation if findings were abnormal before.

Pharmacologic Treatment

Clinically nonfunctioning pituitary adenomas that are associated with elevated serum concentrations of prolactin or growth hormone can be treated with the pharmacologic treatments typically used for those adenomas.

Many clinically nonfunctioning pituitary adenomas, largely gonadotroph adenomas, have been shown to express dopamine receptors,[66] and some studies suggest that dopamine agonist treatment may be useful to treat residual adenoma tissue following removal by surgery. One study showed that cabergoline treatment reduced residual adenoma size in five of nine patients 1 year following surgery.[66] Another study compared regrowth of clinically nonfunctioning adenomas at one hospital that administered dopamine agonist treatment and a nearby hospital that did not.[67] In 55 patients treated with a dopamine agonist beginning soon after surgery, residual adenoma size decreased in a mean follow-up of 8.8 years in 38% of patients but in none of the 60 patients who were not treated. During the same follow-up period, adenoma size increased in 13% of the treated patients and in 47% of the untreated patients.

Gonadotroph adenomas also express somatostatin receptors, perhaps the subtype 3 most abundantly,[68] but treatment of patients who have residual gonadotroph adenoma tissue after surgery does not have clear effects on adenoma size.[69,70]

Agonist analogs of GnRH produce either an agonist effect or no effect on secretion and have no effect on adenoma size.[71,72] Treatment with the GnRH antagonist Nal-Glu GnRH for 6 months suppressed FSH but did not reduce adenoma size.[73]

Observation

Observation alone is a reasonable course for a patient who has a clinically nonfunctioning sellar mass, even one greater than 1 cm, as long as the mass is not associated with neurologic symptoms. If observation is chosen, however, the patient should be followed carefully for possible enlargement of the mass and development of visual impairment. In several retrospective studies of the natural history of clinically nonfunctioning sellar masses greater than 1 cm, increases in size occurred in 20% to 50% of patients in an average of 4 to 5 years.[60,74-76] Patients should also be followed for a possible change in hormonal function, as an increase in size could lead to decreased hormonal secretion, and an adenoma that did not cause detectable hormonal hypersecretion on initial evaluation could do so subsequently.

INTRODUCTION

In the majority of patients with hyperthyroidism, pituitary thyroid stimulating hormone (TSH, thyrotropin) secretion is suppressed as a consequence of autonomous thyroid hormone (TH, thyroxine [T4], triiodothyronine [T3]) production by the thyroid gland, and most commonly arises in the context of Graves disease, toxic multinodular goiter, or a solitary toxic adenoma. However, in a small but important subgroup of patients, TSH production is not suppressed, but is in fact the driver for hyperthyroidism.[1,2] TSH-producing pituitary adenomas (PAs), commonly referred to as thyrotropinomas or TSHomas, are an important cause of such central hyperthyroidism (i.e., neoplastic inappropriate secretion of TSH) and must be differentiated from nonneoplastic inappropriate TSH secretion, as is seen in the syndrome of resistance to thyroid hormone (RTHβ) caused by loss-of-function mutations in human *THRB* (encoding the β isoform of the thyroid hormone receptor [TRβ]).[3,4]

In recent years, increased clinician awareness, combined with more robust laboratory assays and improved cross-sectional imaging, has led to the recognition of previously undisclosed cases, especially microthyrotropinomas that are associated with only mild perturbations of thyroid function. However, because thyrotropinomas remain a rare cause of hyperthyroidism, many clinicians (even in tertiary centers) have only limited experience of their investigation and management, which can be challenging, especially in cases with atypical clinical features and equivocal or negative radiological findings.[2,5] Indeed, confirming the diagnosis, with exclusion of other conditions that can mimic a TSH-secreting PA, is often the point of greatest uncertainty in the management pathway.[6]

In this chapter, we consider current perspectives on the epidemiology and pathophysiology of TSH-producing PAs, review their varied modes of presentation, and provide guidance on the key steps in the diagnostic pathway and therapeutic options for this rare, but important, subgroup of PAs.

EPIDEMIOLOGY

Thyrotropinomas account for approximately 1% of all pituitary tumors in historical surgical and pathological series.[1] However, just as the overall prevalence of clinically relevant PAs is now recognized to be higher than previously suspected (~1:1200 of the general population), findings from a national registry in Sweden covering the interval 1990 to 2010 have shown (1) an age standardized national incidence of 0.15 per one million inhabitants per year, with an increasing incidence over time (0.05 per million per year in 1990–1994, rising to 0.26 per million per year in 2005–2009), and (2) a prevalence rate in 2010 of 2.8 TSH-secreting PAs per million inhabitants.[7] Several factors are likely to have contributed to recent higher detection rates, including: (1) availability in routine clinical laboratories of ultrasensitive and highly specific TSH assays; (2) greater use of combined measurement of free T4 and TSH to screen for suspected thyroid dysfunction; (3) increased availability of high quality pituitary magnetic resonance (MR) imaging; and (4) increased awareness of the condition. At the same time, the proportion of microadenomas has increased. Early case series reported macroadenomas in greater than 80% of patients with TSH-secreting tumours, with up two thirds manifesting extrasellar extension. However, recent studies indicate that micro-TSHomas are being increasingly diagnosed,[7–9] and it seems likely that the balance will be even further redressed with the advent of alternative (e.g., positron emission tomography [PET]) techniques for detecting small functioning tumours.[10] The majority of patients are diagnosed in middle age, with both sexes affected (median age of diagnosis 56 years in the Swedish cohort, with 60.7% women).[7] However, both paediatric and elderly (>80 years) subjects have been described.[1,5,11]

KEY POINTS

- Although thyrotropinomas are less common than other anterior pituitary adenomas, recent studies point to a higher prevalence than previously suspected (2.8 per million). Most arise sporadically, with a peak age at diagnosis between 40 and 60 years, with both sexes affected.

ETIOPATHOGENESIS AND PATHOLOGY

Etiopathogenesis

Under normal physiological conditions, the hypothalamo-pituitary-thyroid axis is tightly regulated to maintain T4 and T3 levels within a narrow range.[12] Thyrotropin-releasing hormone (TRH, a tripeptide: pyroGlu-His-Pro-NH_2) is secreted from parvocellular neurons in the paraventricular nucleus of the hypothalamus in response to low circulating levels of thyroid hormone (TH) or other triggers (e.g., environmental cold exposure, leptin, neuropeptide Y). Binding to the TRH receptor (TRHR, a calcium-mobilizing, rhodopsin family G protein–coupled receptor [GPCR]) on thyrotroph cells in the anteromedial portion of the adenohypophysis results in the synthesis and secretion of TSH through recruitment of Gq/11, triggering the phospholipase C–inositol 1,4,5-trisphosphate/1,2-diacylglycerol pathway, with resultant mobilization of intracellular calcium and activation of protein kinase C.[13,14]

TSH (a glycoprotein hormone heterodimer comprising alpha- and beta-subunits) binds to its cognate receptor (TSHR, also a GPCR) on the basolateral membrane of thyroid follicular cells to stimulate T4 and T3 synthesis and release. TSH exhibits both circadian and pulsatile patterns of secretion, peaking during the evening and early hours of the morning. Luteinizing hormone (LH) and human chorionic gonadotropin (hCG), which share a common alpha-subunit with TSH, can bind and activate the TSH receptor in certain clinical settings, for example, in early pregnancy when hCG levels are very high, with resultant elevation in T4 and T3 and consequent suppression of pituitary TSH release (see later). Thyrotroph cells in the adenohypophysis are also subject to negative regulation by somatostatin (predominantly acting through somatostatin receptor [SSTR] subtypes 1, 2, and 5) and dopamine (via the dopamine subtype 2 receptor). In addition, exposure to supraphysiological glucocorticoids, treatment with opioids, anorexia nervosa, and nonthyroidal illness have all been linked to reduced basal and TRH-stimulated TSH secretion.

T4 is produced in greater abundance (14:1) compared with T3, but the latter is the biologically active form. Conversion of T4 to T3 in peripheral tissues (in particular the liver) is facilitated by the type 1 deiodinase (DIO1), a member of a family of deiodinases (DIO1–3), which also metabolize T4 and T3 to inactive forms. DIO2 expressed in the hypothalamus and pituitary regulates local T3 production to facilitate inhibition of TRH and TSH production as part of a classical negative feedback loop. TH action in target tissues is mediated by two major receptor subtypes—alpha (TRα) and beta (TRβ) and their splice variants—which are members of the steroid nuclear receptor superfamily.[3,4]

Normal thyrotrophs account for only 5% of all anterior pituitary cells,[15] which may, at least in part, explain why thyrotropinomas are rare compared with other anterior pituitary tumor subtypes. The etiopathogenesis of TSH-secreting PAs remains poorly understood. Although the majority arise within the sella, a small number of TSH-secreting adenomas are located within the sphenoid sinus or nasopharynx and considered ectopic.[16,17] Thyrotropinomas have been observed in the context of multiple endocrine neoplasia type 1,[18] McCune–Albright syndrome (because of a somatic activating mutation in the α-subunit of Gs (encoded by *GNAS*),[19] and familial isolated PA (owing to mutation in the aryl hydrocarbon receptor-interacting protein [AIP]),[20] but such cases are rare, and the majority appear to arise sporadically.

Data from analyses of all pituitary tumor subtypes (including a small number of TSH-secreting adenomas) point to clonal expansion from a single transformed cell.[21,22] Evidence of aberrant transcriptional regulation of thyrotrophs (with resultant TSH hypersecretion and unrestrained growth) has been sought but, so far, most studies have proved largely uninformative, including those examining protooncogenes (e.g., *GSP*, *RAS*) and tumor suppressor genes (e.g., *RB*, *P53*).[23,24] The pituitary-specific transcription factor Pit-1 is overexpressed in some TSH-secreting PAs, and might play a role in cell proliferation as well as promoting hormone cosecretion in this subgroup of adenomas.[1,2]

The hallmark of TSH-secreting PAs is constitutive and autonomous secretion of TSH with failure of negative regulation by T3. Several possible molecular mechanisms for impaired negative feedback have been proposed. For example, a somatic loss-of-function mutation in *THRB* (encoding a dominant negative TRβ with impaired T3-mediated regulation of TSH transcription) was identified in one of five thyrotropinomas[25]; aberrant expression of a TRβ4 isoform (capable of functioning as an endogenous antagonist of normal TRβ signaling) was reported in three thyrotropinomas[26]; and disordered deiodinase function (resulting in reduced local pituitary T3 generation) was most pronounced in thyrotropinomas when compared with other pituitary tumor subtypes.[27] However, perhaps counter to this hypothesis, it is noteworthy that the occurrence of thyrotropinoma in subjects with *THRB* RTH (RTHβ) is extremely rare despite life-long aberrant TRβ signaling in these subjects.[28]

Although TRHR is expressed on the majority of thyrotroph tumor cells, the attenuated/absent response of TSH and α-subunit to exogenous TRH administration in many patients with TSH-secreting PAs suggests the TRHR signaling pathway is impaired/nonfunctional in these tumors.

Most thyrotropinomas express SSTR subtypes 1, 2, 3, and 5, with SSTR2 the dominant isoform. However, it seems unlikely that the primary molecular defect resides within this pathway, as depot somatostatin receptor ligand (SRL) therapy rapidly normalizes thyroid function in the majority of patients and may result in tumor shrinkage.[29]

In a recent study, using whole-exome sequencing in a small number of thyrotropinomas, no common driver mutations (either in genes known to predispose to other PA subtypes or amongst novel candidate genes identified in the tumors) were confirmed, suggesting that discrete primary events may underlie tumorigenesis in different patients.[30] Similarly, studies of copy number variations were largely inconclusive.[30]

Pathology

TSH-secreting PAs are classically chromophobic under light microscopy and demonstrate positive immunohistochemical staining for the unique TSH beta-subunit, the common alpha-subunit (ASU), and the transcription factor Pit-1. TSH-secreting macroadenomas are often accompanied by unbalanced hypersecretion of the common ASU, and double-immunostaining studies have suggested the existence of two different types of cells: one secreting ASU alone and another cosecreting the ASU and the TSH beta-subunit.[31]

Normal thyrotrophs share a common lineage with somatotrophs and lactotrophs, with Pit-1 being a key regulator of differentiation and proliferation for each of these three anterior pituitary cell types. Consistent with this, cosecretion of growth hormone (GH) and/or prolactin (PRL) is observed in 25% to 30% of thyrotropinomas (Fig. 9.1) and may be the dominant clinical manifestation, with hyperthyroxinemia and inappropriate TSH secretion only identified during endocrine evaluation. Intriguingly however, not all patients with biochemical evidence of abnormal GH secretion manifest overt acromegaly (Bashari, MacFarlane, Senanayake, Koulouri, Gurnell, unpublished observation). In addition, a subgroup of tumors demonstrate positive immunohistochemical staining for GH and/or PRL, but do not exhibit clinical or biochemical

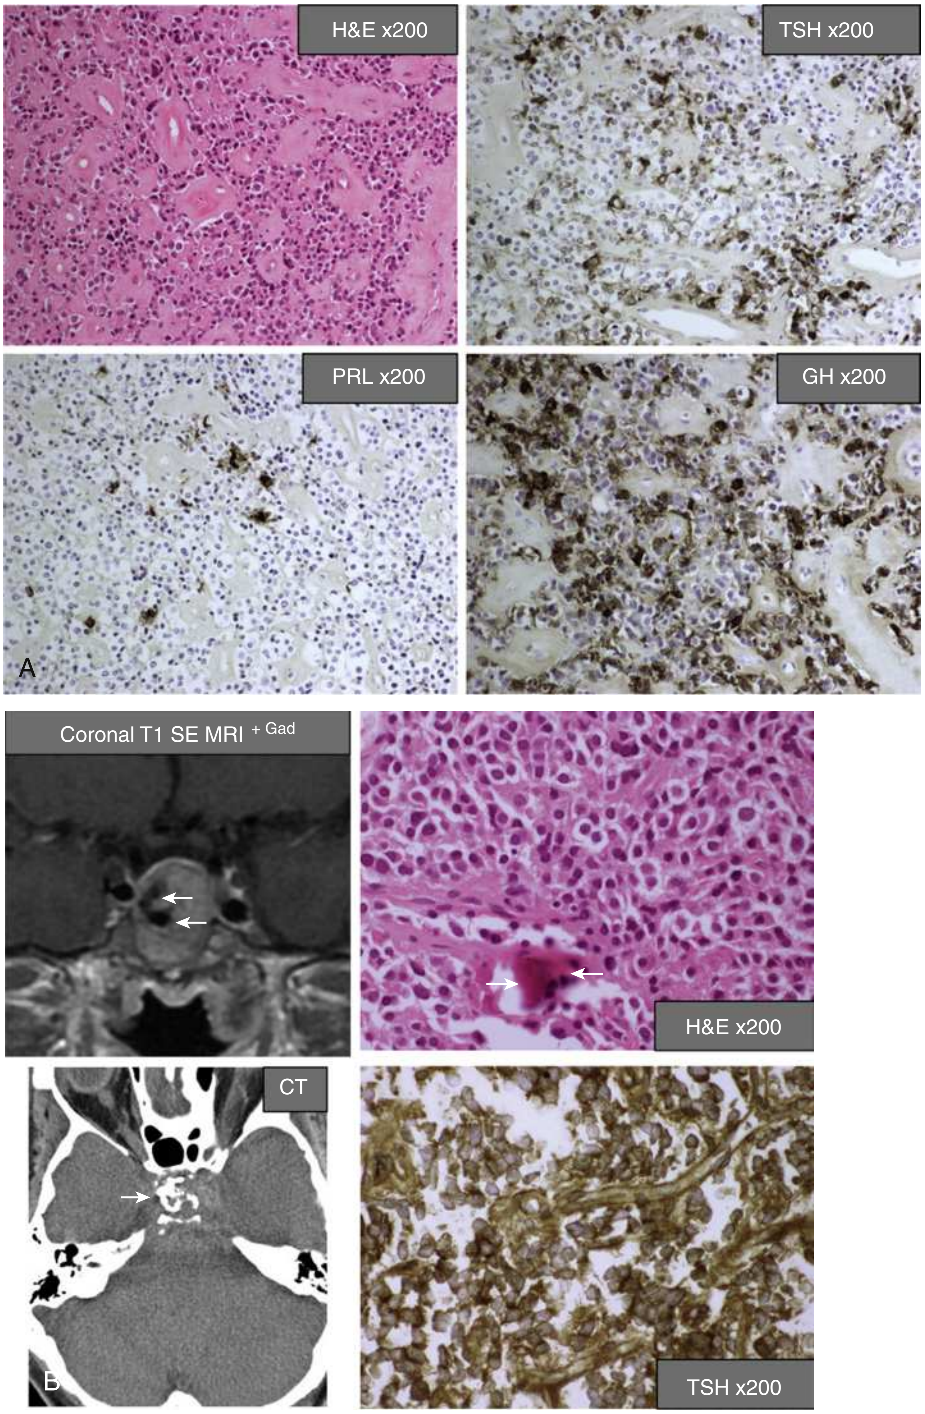

Fig. 9.1 Histological appearances in thyrotropinomas. **A**, Pituitary adenoma demonstrating positive immunohistochemical staining for thyroid-stimulating hormone (*TSH*), prolactin (PRL), and growth hormone (*GH*). **B**, Thyrotropinoma with prominent intratumoral calcification—on magnetic resonance imaging (MRI) a semicircular hypodense area is seen within the right side of the sella *(arrows)*, which could be mistaken for a vascular structure, but which is confirmed as focal calcification on computed tomography (*CT*) *(arrow)*. At surgery, macroscopic calcium deposits were resected, and histology confirmed additional microscopic foci of calcification *(arrows)* with strong immunohistochemical staining for TSH. *H&E*, Hematoxylin and eosin; *SE*, spin echo. (Pathology images provided courtesy of Dr. Kieren Allinson, Department of Neuropathology, Addenbrooke's Hospital, Cambridge.)

acromegaly or hyperprolactinaemia. Similarly, so-called silent thyrotropinomas (clinically nonfunctioning PAs, but with abundant positive TSH beta-subunit staining on immunohistochemistry) are well described,[32] and multihormone-staining (clinically silent) tumors have also been reported.

TSH-secreting PAs are almost always benign, with only a handful of malignant tumors (metastasizing to brain/spine, bone, or lung) reported to date.[33-35] A subgroup of thyrotropinomas are more fibrotic than other pituitary tumors, which has been linked to local secretion of basic fibroblast growth factor by the adenoma cells.[36] In this context, both microscopic and macroscopic calcification ("pituitary stone") may be seen, and can confound the interpretation of MR imaging and make surgical resection more challenging (Fig. 9.1).

Finally, not all TSH-secreting PAs are associated with overt elevation of serum TSH levels. Indeed, it has been estimated that between 30% and 40% of cases have a TSH level that repeatedly falls within the reference range but is inappropriately normal for the ambient raised thyroid hormone levels. This may be explained, at least in part, by increased bioactivity of neoplasm-derived TSH.[1]

KEY POINTS

- The majority of thyrotropinomas occur sporadically, with only a small number of cases arising in the context of genetic disorders known to predispose to pituitary adenomas. Although several molecular mechanisms have been postulated, the etiology of most thyroid-stimulating hormone (TSH)-secreting adenomas remains unknown. Approximately 25% of tumors cosecrete growth hormone and/or prolactin, but not all are associated with clinical sequelae. Ectopic TSH-secreting pituitary adenomas and TSH-secreting pituitary carcinomas are both described, but are extremely rare.

CLINICAL PRESENTATION

Clinical features of hyperthyroidism secondary to a TSH-secreting PA overlap those seen in primary hyperthyroidism (and include palpitations/arrhythmias, tremor, heat intolerance, weight loss, sleep disturbance, etc.), but without disease-specific (e.g., Graves ophthalmopathy or dermopathy) manifestations.[1,2,5] In some patients, symptoms and signs remain relatively unchanged over long intervals (≥10 years), whereas in others they are progressive. Clinical features are often surprisingly modest, reflecting milder perturbations in T4 and T3 levels than are typically seen in primary hyperthyroidism owing to Graves disease, toxic nodular disease, or thyroiditis. Indeed, some individuals appear to be asymptomatic even after direct questioning. Importantly, however, following successful treatment, a number of these patients report an improvement in their well-being, coinciding with resolution of previously unrecognized clinical symptoms (Bashari, MacFarlane, Senanayake, Koulouri, Gurnell, unpublished observation). The estimated mean latency between onset of hyperthyroidism and establishment of the diagnosis is typically around 4 to 5 years (but may exceed a decade). In mixed secreting tumors, clinical features of growth hormone excess (acromegaly) and hyperprolactinemia (hypogonadism, galactorrhea) may be seen or even dominate the presentation.

Goiter and/or thyroid nodules are found in many patients and likely reflect sustained TSH stimulation of thyroid follicular cells over many years.[37,38] The cooccurrence of differentiated thyroid carcinoma has been described in a small number of cases.[39,40] Autoimmune thyroid dysfunction may also coexist and give rise to diagnostic uncertainty.[41,42]

In early case series, compressive symptoms (such as visual field defects [80%] and headaches [20%]) prevailed over those owing to hyperthyroidism. However, this is no longer the case, as many patients present at an earlier stage, and the proportion of microadenomas is increasing.[7-9] Unilateral exophthalmos because of orbital invasion by the pituitary tumor is very rare, but must be distinguished from asymmetric exophthalmos of Graves disease. In macroadenomas, concomitant hypopituitarism (e.g., hypogonadism, hypoadrenalism) may be present. TSH-secreting PAs have been reported in pregnant women, in patients with multiple endocrine neoplasia type 1, and in atypical McCune–Albright syndrome.[18,19,43]

KEY POINTS

- As with other functioning pituitary adenomas, thyroid-stimulating hormone–secreting tumors may manifest with evidence of hormone excess (central hyperthyroidism), local compressive features (e.g., visual loss), and/or hypopituitarism. In contrast to primary hyperthyroidism, symptoms and signs can be surprisingly mild (even absent), and features of hormone cosecretion (e.g., acromegaly, hyperprolactinemia) may predominate. Coexistent thyroid nodules/cancer and autoimmune thyroid dysfunction may complicate the clinical presentation.

DIFFERENTIAL DIAGNOSIS

In theory, establishing the diagnosis of a TSH-secreting PA should be relatively straightforward, given the distinctive laboratory finding of inappropriately nonsuppressed TSH in the face of overt hyperthyroidism (with increased free T4 and free T3). However, this biochemical pattern is not restricted to thyrotropinomas, and it is often necessary to consider and actively exclude other possible causes before proceeding with targeted intervention (Table 9.1).

KEY POINTS

- Thyroid-stimulating hormone (TSH)-secreting pituitary adenomas have a distinctive laboratory fingerprint: raised thyroid hormones with inappropriate, nonsuppressed TSH. However, there are a multitude of other causes of hyperthyroxinemia with detectable TSH, and these must be carefully considered/excluded before concluding that the patient has a thyrotropinoma.

INVESTIGATION

Step 1 – Clinical Assessment

Careful clinical evaluation is an essential first step in the investigation of any patient with a suspected TSH-secreting PA. Specifically, it is important to: (1) identify potential confounding factors (including intercurrent illness, medications/supplements [e.g., amiodarone, heparin, biotin]); (2) make a judgment as to the clinical thyroid status of the patient (i.e., hypothyroid, euthyroid, or hyperthyroid); and (3) assess for other features that might point to a TSH-secreting adenoma (e.g., coexistent acromegaly or hyperprolactinemia, local suprasellar/parasellar mass effect) or, alternatively, suggest the possibility of laboratory assay artifact (e.g., falsely detectable serum TSH in a patient with dysthyroid eye signs and a thyroid bruit owing to Graves disease).

Step 2 – Exclusion of Laboratory Assay Interference

Thyroid function tests are amongst the most commonly requested biochemistry investigations. Both THs and TSH are typically measured using immunoassays on high-throughput automated analyzers. Such platforms are susceptible to multiple different forms of assay interference (Table 9.1), and close liaison with the clinical chemistry laboratory is therefore critically important to avoid inappropriate further investigation and treatment. Confirmation that free thyroid hormone levels (free T4 and T3) are genuinely raised may require referral to a reference laboratory with the ability to perform a two-step (back titration) assay, equilibrium dialysis, or mass spectrometry, which allow the detection of heterophilic or antiiodothyronine antibodies or variant binding proteins (e.g., albumin in familial dysalbuminemic hyperthyroxinemia; transthyretin in dystransthyretinemic hyperthyroxinemia). TSH dilution studies, immunosubtraction (using

TABLE 9.1 **Causes of Elevated Serum Thyroid Hormones With Nonsuppressed Thyroid-Stimulating Hormone**

Mechanism	Laboratory findings	Clinical context/example(s)
Increased thyroid hormone binding capacity	• raised total T4 & T3 • normal free T4 & T3 • nonsuppressed/normal TSH	• pregnancy • estrogen-containing oral contraceptive/hormone replacement therapy
Laboratory assay interference—falsely elevated free TH in a euthyroid individual	• raised free T4 ± T3—but with potential variability across assay platforms • normal TSH	• heterophile antibodies • antiiodothyronine antibodies • familial dysalbuminemic hyperthyroxinemia (FDH)[a] • familial dystransthyretinemic hyperthyroxinemia (DTTRH)[a]
Laboratory assay interference—falsely nonsuppressed TSH in a patient with genuine hyperthyroxinemia	• raised total and free T4 & T3 • detectable or raised TSH – but with potential variability across assay platforms	• heterophile antibodies • human antianimal antibodies • macro-TSH
Requirement for mildly elevated serum T4 to maintain normal serum T3 and TSH while taking exogenous thyroxine therapy	• raised free T4 • normal free T3 • normal TSH	• thyroxine replacement therapy in primary hypothyroidism
Inconsistent TH administration with dosing immediately before laboratory testing	• raised free T4 ± T3—but may vary depending on timing of blood sampling • raised TSH	• intermittent/erratic thyroxine administration
Inhibition of deiodinase function	• raised free T4 • normal free T3 • normal TSH	• amiodarone therapy
Displacement of TH from binding proteins[b]	• Raised free T4 • Normal/raised free T3 • normal TSH	• heparin therapy
Altered hypothalamic-pituitary-thyroid axis physiology; altered binding protein status	• raised free T4 ± T3—but with potential variability across assay platforms and phase of illness • nonsuppressed TSH	• acute psychiatric disorder • neonatal period
Neoplastic inappropriate TSH secretion	• raised total and free T4 & T3 • normal/raised TSH	• TSH-secreting pituitary adenoma
Impaired TH action: loss-of-function mutations in *THRB*	• raised free T4 & T3 • normal TSH	• TRβ resistance to thyroid hormone (*THRB* RTH)
Impaired TH action: loss-of-function mutations in *THRA*	• normal/low free T4 • raised free T3 • normal TSH	• TRα resistance to thyroid hormone (*THRA* RTH)
Impaired TH transport: loss-of-function mutations in *SLC16A2* (*MCT8*)	• normal/low free T4 • raised free T3 • normal TSH	• Allan–Herndon–Dudley syndrome (MCT8 deficiency)
Impaired TH metabolism: loss-of-function mutations in *SECISBP2* (*SBP2*)	• raised free T4 • normal/low free T3 • normal TSH	• SECISBP2 deficiency syndrome (typically associated with widespread selenoprotein deficiencies)

[a] FDH and DTTRH are also both associated with an increase in total TH levels because of the increased binding capacity of mutant albumin and transthyretin, respectively; at the same time, artifactual elevation in free T4 (and in some instances free T3) is observed on some laboratory platforms.

[b] Both fractionated and unfractionated heparin can cause artifactual elevation in measured free T4 (± free T3) owing to displacement from albumin binding sites by free fatty acids (generated in response to heparin-mediated activation of endothelial lipoprotein lipase).

MCT8, Monocarboxylate transporter 8; *SECISBP2*, selenocysteine insertion sequence binding protein 2; *SLC16A2*, solute carrier family 16 member 2; *T3*, triiodothyronine; *T4*, thyroxine; *TH*, thyroid hormone; *TSH*, thyroid-stimulating hormone.

polyethylene glycol or protein G/A), or gel filtration chromatography can be used to exclude interference in the TSH assay.[44]

Step 3 – Distinguishing a Thyroid-Stimulating Hormone–Secreting Pituitary Adenoma From TRβ Resistance to Thyroid Hormone

Once genuine hyperthyroxinemia with nonsuppressed TSH has been confirmed, the main task is to distinguish a TSH-secreting PA from rare genetic disorders of thyroid hormone transport, metabolism or action, in particular RTHβ). The degree of clinical thyrotoxicosis and the magnitude of elevation of thyroid hormone and TSH levels show considerable overlap when comparing cohorts of patients with thyrotropinomas and RTHβ. Accordingly, other investigations are often employed to distinguish between these two entities (Table 9.2).

Family History/Genetic Screening. The majority of TSH-secreting PAs are sporadic, with only occasional cases reported in the context of familial PA syndromes. In contrast, RTHβ is an autosomal dominant disorder, and affected family members can be readily identified through thyroid function testing, which then guides subsequent genetic screening. However, between 10% and 15% of patients with

TABLE 9.2 Distinguishing Between Thyroid-Stimulating Hormone–Secreting Pituitary Adenoma and TRβ Resistance to Thyroid Hormone (TRβ RTH)

	TSH-Secreting Pituitary Adenoma	TRβ RTH
Family history	typically no relevant family history	often positive (either known or identified during investigation)
Genetic analysis (*THRB* gene screen)	negative[a]	positive in 85%–90% of cases
Serum T4 and T3	elevated[b]	elevated[c]
Serum TSH	normal or elevated	normal or mildly elevated
Circadian TSH secretion	absent	preserved
SHBG	elevated (but may be normal in tumors with GH cosecretion and in some microthyrotropinomas)	normal (but may be elevated by other factors, e.g., combined oral contraceptive use)
ASU	normal or elevated	normal
ASU:TSH molar ratio	normal or elevated	normal
Response to exogenous TRH stimulation	absent/attenuated	preserved/exaggerated
Response to exogenous L-T3 suppression	absent/attenuated	retained (although may be incomplete)
Response to trial of depot SRL therapy	rapid and sustained suppression of TSH in majority of cases (with restoration of euthyroidism or induction of hypothyroidism)	no effect[d]
Features of acromegaly and/or hyperprolactinemia	present in 25%–30% of cases	absent
MR imaging	adenoma (although some microadenomas may not be visualized on standard clinical MR imaging)	normal (although incidentalomas may be identified)

[a] Two cases of apparent coexistent RTHβ and a TSH-secreting pituitary adenoma have so far been reported.
[b] Occasionally, serum free T4 and/or free T3 may intermittently fall within the upper part of the laboratory reference range in a patient with a thyrotropinoma.
[c] In a small subgroup of patients with RTHβ, serum free T3 is not overtly elevated outside the reference range.
[d] In RTHβ there may be a transient minor reduction in thyroid hormone and TSH levels immediately after commencing depot SRL therapy, but this is not sustained.
ASU, Alpha-subunit; *GH*, growth hormone; *L-T3*, lio-thyronine; *MR*, magnetic resonance; *SHBG*, sex hormone–binding globulin; *SRL*, somatostatin receptor ligand; *T3*, triiodothyronine; *T4*, thyroxine; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone.

RTHβ do not harbor a demonstrable mutation in *THRB* (see Chapter 81: Resistance to Thyroid Hormone).

Alpha Subunit and Alpha Subunit to Thyroid-Stimulating Hormone Molar Ratio. In traditional case series, a raised serum ASU level and increased ASU:TSH molar ratio were considered important diagnostic markers for thyrotropinoma. The ASU:TSH molar ratio is recommended to mitigate the potential confounding effects of raised gonadotrophin levels (e.g., in postmenopausal women), reflecting the shared common alpha-subunit with LH and FSH. However, in this context, the population reference range for ASU:TSH molar ratio is so wide[45] as to render it of limited value for the detection of all but the most obvious macroadenomas. As a general rule, a raised ASU (and/or ASU:TSH molar ratio) may help to support suspicions of a thyrotropinoma, but a normal result does not exclude the possibility.

Sex Hormone-Binding Globulin. Hepatic production of sex hormone-binding globulin (SHBG) is under direct thyroid hormone (positive) regulation via the TRβ1 isoform of the receptor. In RTHβ the liver is therefore resistant, and SHBG levels typically fall within the age- and gender-related reference range. In contrast, in the presence of a TSH-secreting tumor, elevated thyroid hormone levels cause hepatic thyrotoxicosis with raised SHBG. Unfortunately, however, normal SHBG levels may sometimes be seen, especially in microthyrotropinomas or when there is cosecretion of growth hormone. Similarly, other factors (e.g., oral estrogen therapy, pregnancy, liver dysfunction, anorexia) may cause an elevated SHBG in RTHβ.

Dynamic Testing. The use of dynamic testing can be particularly helpful in discriminating between RTHβ and a TSH-secreting PA.[1,2,44]

1. TRH test (200 mcg intravenously) (not available in all countries):
   - Thyrotropinoma: absent or attenuated (<4-fold) rise in TSH
   - RTHβ preserved or exaggerated TSH response
2. Depot SRL (e.g., lanreotide autogel 90–120 mg or sandostatin LAR 20–30 mg every 4 weeks for two to three injections):
   - Thyrotropinoma: rapid and sustained normalization of free T3, free T4, and TSH levels in 80% to 90% of patients; some patients may even develop central hypothyroidism requiring dose titration and/or levothyroxine supplementation.[29,46]
   - RTHβ no significant change in free TH or TSH levels (although a transient nonsustained diminution may be observed if levels are checked shortly after initiating treatment[46])

   Interestingly, the short-acting octreotide suppression test (single dose of 100 mcg subcutaneously) is less discriminatory, with TSH levels partially suppressing (~50%) in some patients with RTHβ, as well as in the majority of TSH-secreting PAs.[46]
3. Liothyronine (L-T3) suppression test (various protocols exist, including progressive dose escalation or fixed dosing [e.g., 100 mcg/day] over a 10-day period):
   - Thyrotropinoma: absent or only slight reduction of TSH
   - RTHβ: TSH suppression is marked (although not always complete)

In practice, the L-T3 suppression test is often reserved for those cases in which results remain equivocal despite extensive investigation, or for detecting low level residual or recurrent disease following pituitary surgery.[1,6] The test is not suitable for those with known or suspected cardiac disease (arrhythmias, ischemia, heart failure) or a history of major psychiatric disease.

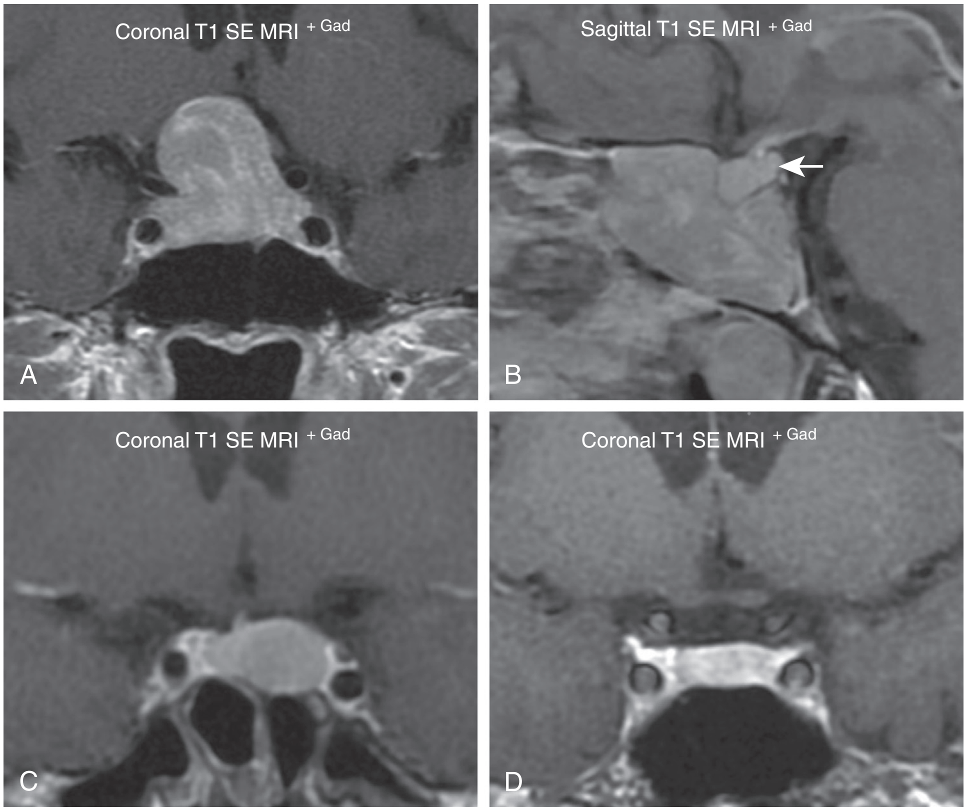

Fig. 9.2 Spectrum of thyroid-stimulating hormone–secreting pituitary adenomas. **A**, Macroadenoma with predominant suprasellar extension compressing the optic chiasm. **B**, Macroadenoma filling the sphenoid sinus—note how the adenoma appears discrete from the normal pituitary gland, which is situated superiorly in the sella *(arrow)*, raising the possibility of an extrasellar ectopic origin. **C**, Left-sided predominantly intrasellar macroadenoma. **D**, No visualized adenoma. *Gad*, Gadolinium; *SE*, spin echo; *T1*, T1-weighted; *MRI*, magnetic resonance imaging.

Table 9.2 summarizes the typical findings in TSH-secreting PA and RTHβ across the various tests.

Step 4 – Pituitary Imaging

Once the diagnosis of a TSH-secreting PA has been confirmed, attention turns to tumor localization. The finding of a pituitary microadenoma in a patient with inappropriate secretion of TSH, although strongly suggestive, is not diagnostic of a TSH-secreting pituitary tumor, as pituitary incidentalomas are found on MR imaging in up to 10% of the general population. In contrast, incidental macroadenomas are much less commonly encountered. Indeed, some clinicians reason that, if a pituitary macroadenoma is found in a patient with raised free thyroid hormone levels and nonsuppressed TSH, then it is reasonable to proceed directly to surgery without additional confirmatory testing. However, in our experience this will occasionally result in unnecessary surgery, especially if due diligence in excluding laboratory assay interference is not undertaken. We therefore recommend that imaging is performed only when there is clear clinical and laboratory evidence of the presence of neoplastic inappropriate TSH secretion (± local mass effect).

In patients with TSH-secreting PAs there is no correlation between serum TSH and tumor size. In older case series, patients commonly presented with macroadenomas with suprasellar and sphenoidal extension, whereas in more recent series microadenomas feature much more frequently.[7-9] Indeed, it is now clear that thyrotropinomas exhibit a spectrum ranging from large invasive (even giant) tumors through to microadenomas that cannot be readily visualized using conventional MR sequences (analogous to some Cushing microadenomas) (Fig. 9.2). For the latter, various approaches have been employed to aid localization of the tumor (including inferior petrosal sinus sampling with TRH stimulation[9]) and octreotide scintigraphy.[9] However, the most promising approach appears to be functional/molecular imaging with ^{11}C-methionine PET–computed tomography (CT) coregistered with volumetric MRI, which may permit precise localization of the tumor (Fig. 9.3), especially when performed pre-and postsomatostatin analog therapy.[10]

KEY POINTS

- Diagnosis of a thyroid-stimulating hormone–secreting pituitary adenoma requires a multifaceted approach that combines clinical, laboratory, genetic, and radiological investigations in four sequential steps: (1) clinical assessment to determine thyroid status, exclude confounding intercurrent illness or medications, and identify associated clinical features (e.g., growth hormone or prolactin excess); (2) exclusion of laboratory assay interference; (3) distinction from TRβ resistance to thyroid hormone; (iv) cross-sectional (magnetic resonance imaging, computed tomography) with or without molecular imaging of the sella and parasellar regions to localize the tumor.

MANAGEMENT

In most patients with TSH-secreting pituitary tumors, the goals of therapy are similar to those for other functioning PAs, namely: (1)

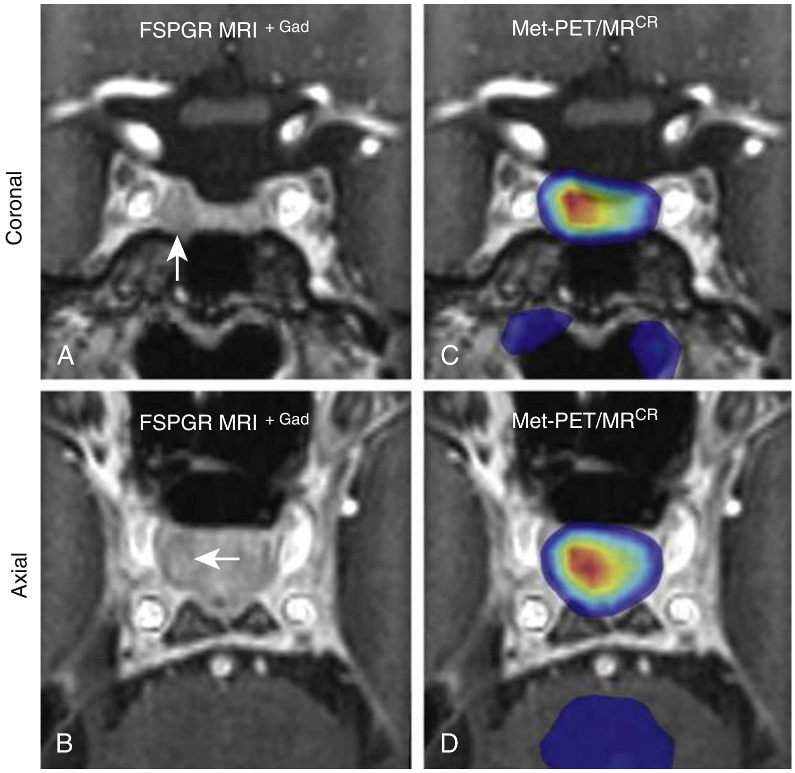

Fig. 9.3 Confirmation of the site of a microadenoma using volumetric magnetic resonance imaging (*MRI*) and molecular (functional) imaging with ^{11}C-methionine positron emission tomography (*PET*) in a patient in whom standard clinical magnetic *SE*, spin echo; (*MR*) sequences pre- and postcontrast had failed to identify a thyrotropinoma. **A** and **B**, Volumetric (*FSPGR*) MR sequences (1-mm slices) identify a possible right-sided microadenoma adjacent to the cavernous sinus *(arrows)*. **C** and **D** ,^{11}C-methionine PET/computed tomography (CT) coregistered with FSPGR MRI demonstrates avid tracer uptake at the site of the suspected lesion. Transsphenoidal surgery and histological analysis confirmed a right-sided thyroid-stimulating hormone–secreting microadenoma. *Gad*, Gadolinium; *FSPGR*, fast spoiled gradient recalled acquisition; *Met-PET/MR*^{CR}, ^{11}C-methionine PET/CT coregistered with volumetric MRI.

restoration of euthyroidism; (2) amelioration/reversal of local compressive symptoms/signs; and (3) correction of hypopituitarism. Early diagnosis helps prevent systemic complications (e.g., cardiac arrhythmias, osteoporosis) and may be associated with improved surgical cure rates.

Transsphenoidal surgery remains the treatment of choice. Historically, pituitary surgery has been reported to achieve normalization of thyroid hormone secretion and resolution of the pituitary mass in approximately 50% of patients, achieve normalization of thyroid parameters despite incomplete tumor removal in approximately 25% of patients, and be unsuccessful (with persistent hyperthyroidism and residual adenoma) in nearly 30% of cases. However, improved surgical remission rates have been reported in more recent series, likely reflecting improved surgical techniques and earlier diagnosis.[47] In addition, surgical cure rates for microadenomas are considerably higher and approach 90% in experienced centers.[48]

The success of treatment is also dependent on the criteria used. It has been proposed that an early indicator of "cure" may be an undetectable TSH concentration 7 days after surgery (when the normal thyrotrophs remain suppressed as a consequence of prolonged exposure to raised circulating thyroid hormone levels).[47] However, many patients are now treated with somatostatin analogs before surgery, often with rapid normalization of hyperthyroidism, which may therefore allow recovery of normal thyrotroph function and, at the same time, confound interpretation of early postoperative testing. Accordingly, normalization of dynamic tests (e.g., TRH test, T3 suppression test) may represent a better (later) test of remission. In any case, long-term follow-up is necessary to detect relapse and recurrence.

Primary medical therapy is increasingly recognized as a viable alternative to pituitary surgery in some patients with TSH-secreting pituitary tumors. Dopamine agonists are an effective treatment in true mixed TSH/PRL-secreting PAs, whereas success is limited when bromocriptine is used in patients with pure TSH-secreting PAs.[49] In contrast, depot SRLs (e.g., octreotide LAR or lanreotide ATG) suppress TSH secretion in approximately 90% of TSH-secreting PAs and normalize thyroid hormone levels in approximately 75% to 90% of patients. Moreover, it has been estimated that approximately 15% of patients will develop central hypothyroidism requiring dose titration and/or levothyroxine supplementation.[29] Interestingly, significant tumor shrinkage (≥20%) is observed in only approximately 50% of cases, and total resolution of a macroadenoma with maintenance of long-term remission in response to somatostatin analog therapy has been reported only rarely.[50] As a general rule, the effects of SRLs are reversible, and treatment must therefore be continued long-term. The development of tachyphylaxis, requiring dose escalation to maintain biochemical control, is seen in up to 10% of cases. True SRL resistance may be observed in a small number of patients.[51] The second-generation SRL pasireotide may be considered for treatment resistant cases.[52] Long-term SRL therapy is expensive and may be associated with side effects such as cholelithiasis and carbohydrate intolerance. Accordingly, although some patients and their clinicians may elect to pursue long-term primary SRL therapy, for many patients it remains a bridge to surgery (allowing anesthesia to proceed safely), and as adjunctive therapy when surgery is unable to achieve full remission, or while awaiting the beneficial effects of radiotherapy.

It is appropriate to briefly mention conventional antithyroid drug therapy, which may be used for a short duration in preparation for surgery. However, concerns remain that longer-term use may predispose to tumor expansion (Nelson-like phenomenon),[1] and for that reason permanent thyroid ablation is also generally best avoided, although may occasionally be indicated in those with recalcitrant arrhythmias or cardiac failure.

Conventional radiotherapy and stereotactic radiosurgery have also been employed in the management of TSH-secreting pituitary tumors, especially when surgery and/or medical therapy has proved unsuccessful.[53] However, the number of reported cases, especially using modern radiotherapy techniques, remains relatively small. As with other pituitary tumor subtypes, allowing for the time lapse required for the full effect to be realized, and the potential for late side effects (e.g., hypopituitarism, second tumor, possible increased cerebrovascular disease), radiotherapy is generally reserved for the small number of cases in which combination surgery and medical therapy are unable to achieve satisfactory biochemical and/or tumor control.

KEY POINTS

- For thyroid-stimulating hormone–secreting pituitary microadenomas, transsphenoidal surgery by an experienced pituitary surgeon is generally preferred and achieves complete/sustained remission in a significant proportion of cases. For macroadenomas, surgical success is influenced by several factors, including surgical expertise, tumor size, and extent of cavernous sinus invasion. Somatostatin receptor ligand therapy may be used before surgery to permit safe anesthesia, or when there is persistent disease—either as long-term treatment or while awaiting the effects of radiotherapy. Antithyroid drugs can help achieve control of hyperthyroidism pending other interventions, but are typically restricted to short-term use to minimize the risk of tumor expansion.

CONCLUSIONS

Although thyrotropinomas remain one of the rarest anterior PA subtypes, recent studies suggest they are more common than previously reported, with a greater proportion of microadenomas now diagnosed. However, understanding of the etiopathogenesis of these tumors remains limited, and further collaborative studies across major centers are likely to be required to improve understanding of the molecular basis for the development of tumoral inappropriate TSH secretion. Combined clinical, laboratory, genetic, and radiological investigation allows the diagnosis of a TSH-secreting PA to be made with confidence, and in the knowledge that other causes of hyperthyroxinemia with nonsuppressed TSH have been robustly excluded. Molecular imaging shows promise for the localization of small tumors that are beyond the resolution of existing MR imaging. Transsphenoidal surgery remains the treatment of choice, although depot somatostatin analog therapy is now established as a key component in the management pathway: either pre- or postsurgery, or increasingly as long-term primary medical therapy.

HISTORY AND RECENT DEVELOPMENTS OF TRANSSPHENOIDAL SURGERY

The advent of transsphenoidal pituitary adenoma surgery dates back over a century. Since that time, the safety and efficacy have improved tremendously. The first major improvement came in the 1960s with the introduction of the operating microscope and fluoroscopy. These two advances significantly improved operative field illumination and magnification and provided a rudimentary degree of neuronavigation. Selective adenomectomy and pituitary gland preservation became increasingly possible, resulting in a marked improvement in patient outcomes. The era of endoscopic transsphenoidal surgery began in the late 1990s, bringing with it further improvements in illumination, image quality, viewing angle, and dexterity (Fig. 10.1).[1-5] Since then, many other important technical strides have been made, including utilization of the Doppler probe to localize the parasellar internal carotid arteries (ICAs) and avoid ICA injury; pseudocapsular dissection technique for maximizing the probability of remission/resection; greater appreciation of cavernous sinus (CS) anatomy and adenoma invasion patterns; intraoperative neurophysiological monitoring for cranial nerves; and enhanced skull base closure techniques to avoid cerebrospinal fluid (CSF) leaks and meningitis. Since 2013, national practice trends confirm that a majority of pituitary adenoma operations are now performed fully endoscopically.[6] From an organizational standpoint, the concept of multidisciplinary teams including neurosurgery, endocrinology, otolaryngology, neuroophthalmology, radiation oncology, neuroradiology, and neuropathology has been promoted to optimize management for this complex patient population.[7]

SURGICAL INDICATIONS AND GOALS OF SURGERY

The most common pituitary pathologies are pituitary adenomas, Rathke's cleft cysts (RCCs), and craniopharyngiomas. Surgical indications include: (1) pituitary or sellar mass lesions causing mass effects on surrounding structures resulting in symptoms such as hypopituitarism, visual loss, diplopia and/or headache, (2) hypersecreting adenomas leading to Cushing disease, acromegaly/gigantism, secondary hyperthyroidism, or hyperprolactinemia (refractory or intolerant of medical therapy), or (3) pituitary apoplexy, which may occur in endocrine-active and -inactive adenomas, as well as occasionally in RCCs (Table 10.1).

KEY POINTS

- The endoscopic endonasal approach is the predominant technique used for all sellar and parasellar tumors.

Pituitary Adenoma

Pituitary adenomas are broadly categorized based on size, invasiveness, and hormonal production. Microadenomas are less than 1 cm in maximal diameter, macroadenomas are 1 cm or greater, and giant adenomas are 4 cm or greater (Fig. 10.2). Degree of invasiveness into the CS is most commonly categorized with the Knosp grading system, and is based on coronal magnetic resonance imaging (MRI) sellar images. This grading system is increasingly used as an important parameter of surgical resectability, with grade 0 to 2 adenomas having no or minimal CS invasion and grade 3 to 4 adenomas having

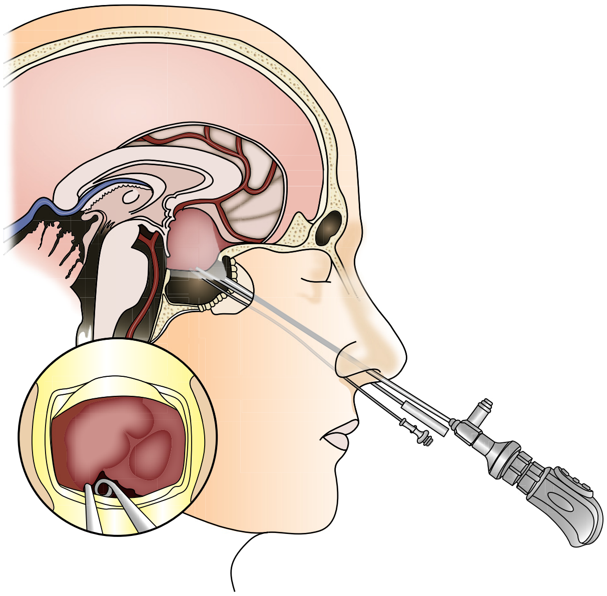

Fig. 10.1 Given the superior panoramic, high-definition view, the endoscopic endonasal approach with a rigid 4-mm endoscope is the preferred technique for removal of pituitary adenomas, Rathke's cleft cysts, and most craniopharyngiomas.

TABLE 10.1 Indications for Pituitary Surgery

1. Relief of mass effect
    - Headache
    - Hypopituitarism
    - Vision loss
    - Other cranial neuropathies
    - Headache
    - Hypothalamic dysfunction
2. Hypersecreting endocrinopathy
    - Acromegaly/gigantism (GH)
    - Cushing disease (ACTH)
    - TSH-secreting adenoma
    - Prolactinoma (PRL; refractory to medical management)
3. Pituitary apoplexy

GH, Growth hormone; *ACTH,* adrenocorticotropic hormone; *PRL*, prolactin; *TSH*, thyroid-stimulating hormone.

progressively greater CS invasion.[8] From an endocrine perspective, endocrine-inactive adenomas are without hormonal hypersecretion, and endocrine-active adenomas include patients with hypersecretion symptoms of Cushing disease with elevated/autonomous adrenocorticotropic hormone (ACTH) and cortisol, acromegaly/gigantism with elevated growth hormone (GH) and insulin like growth factor 1 (IGF-1), prolactinomas with elevated prolactin, and thyrotropinomas with elevated thyroid-stimulating hormone (TSH) and T4/T3. Importantly, as adenoma size increases, so generally does the invasiveness. However, even small endocrine-active adenomas such as those causing Cushing disease or prolactinomas can have grade 3 or 4 CS invasion.

Surgery is considered first-line therapy for all symptomatic endocrine-inactive and endocrine-active pituitary adenomas except prolactinomas, which are generally treated initially with dopamine agonists, either cabergoline or bromocriptine. As described in Chapter 4, medical therapy with dopamine agonists is effective in normalizing serum prolactin levels in approximately 95% and 80% of microprolactinomas and macroprolactinomas, respectively, with resultant tumor shrinkage in most patients.[9] In patients with prolactinomas that are refractory to medical therapy or in whom significant side-effects preclude consistent dosing, endonasal surgery should be considered. Additionally, in patients with prolactinomas who present with apoplexy, particularly those with visual or extraocular movement deficits, urgent endonasal surgery is generally recommended.

Endocrine-inactive microadenomas are often asymptomatic, while macroadenomas typically present with symptoms related to mass effects on adjacent neurological structures. Symptoms may include headache, vision loss (classically bitemporal hemianopia), hypopituitarism, cranial nerve palsy, pituitary apoplexy, and rarely hydrocephalus. Serum prolactin levels may be elevated because of interruption of the inhibitory tuberoinfundibular dopamine pathway, known as the stalk effect. In our recent series on patients aged 65 years or older with pituitary adenomas, approximately 25% did not require surgery and were successfully managed conservatively.[10]

In all operative cases, surgical goals include: (1) maximal safe adenoma resection with biochemical remission and/or relief of mass effect on surrounding structures, (2) preservation and/or restoration of normal pituitary gland function, (3) effective reconstruction of the sellar floor/skull base, and (4) avoidance of complications (Table 10.2, Fig. 10.3).

KEY POINTS

- A multidisciplinary approach to patient selection is paramount, including assessments from neurosurgery, otolaryngology, endocrinology, radiology, neuroophthalmology, and anesthesiology.

Rathke's Cleft Cyst

The majority of patients harboring RCCs are asymptomatic; however, larger cysts can lead to headache, hormonal disturbances (including hypopituitarism or hyperprolactinemia) or visual loss (Fig. 10.4). When

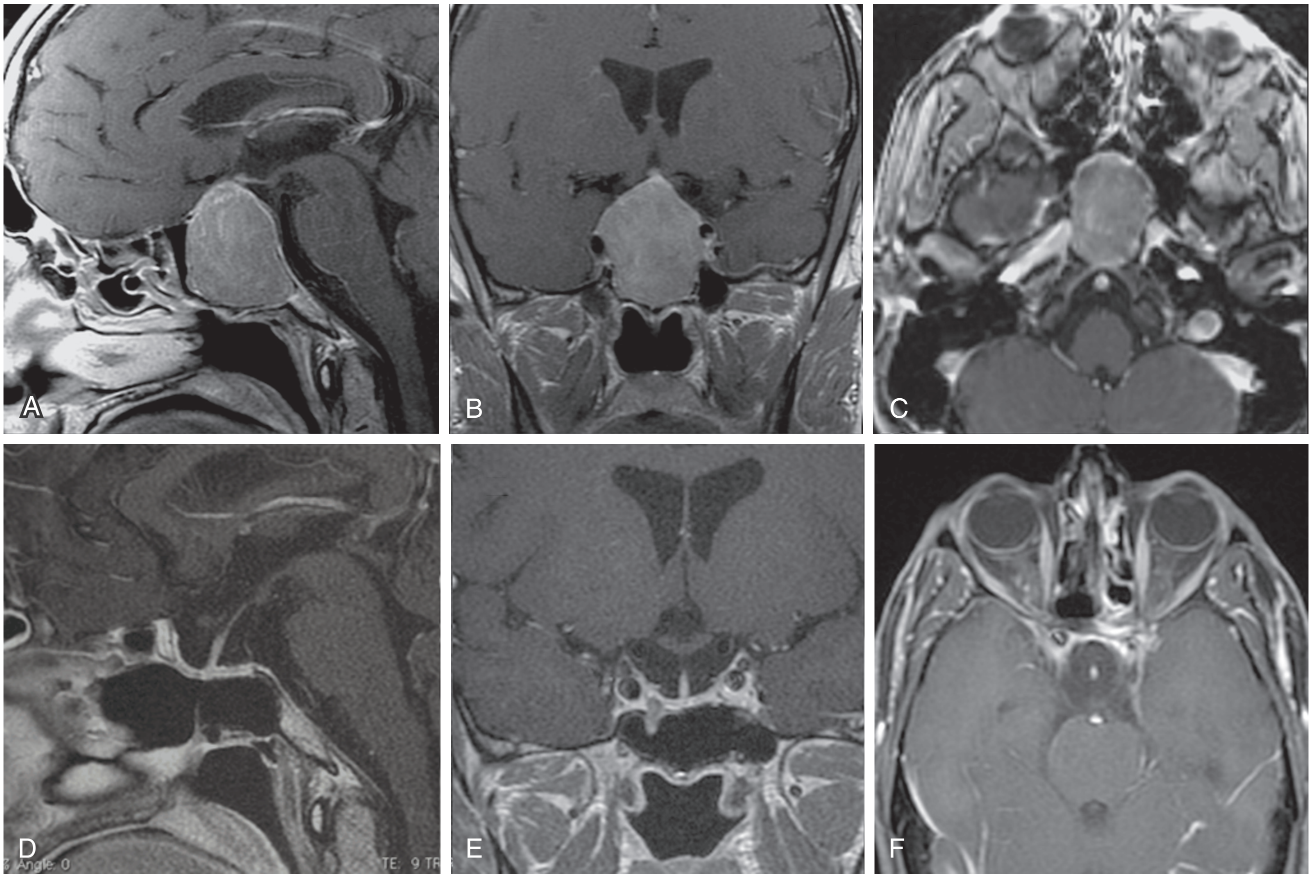

Fig. 10.2 A 51-year old man with an endocrine-inactive pituitary macroadenoma. Preoperative (**A–C**) magnetic resonance imaging (MRI) shows severe gland elevation. His postoperative MRI (**D–F**) 4 years after endoscopic resection shows gross total removal without recurrence and gland reexpansion. His preoperative hypopituitarism resolved after surgery.

TABLE 10.2 Surgical Goals for Pituitary Surgery

- Biochemical remission for hypersecreting endocrinopathies
  - Acromegaly/gigantism (GH)
  - Cushing disease (ACTH)
  - TSH-secreting adenoma
  - Prolactinoma (PRL; refractory to medical management)
- Relief of mass effect
  - Hypopituitarism
  - Vision loss
  - Other cranial neuropathies
  - Headache
  - Hypothalamic dysfunction
  - Pituitary apoplexy
- Preservation of normal pituitary gland function
- Effective closure of sella and/or skull base defect
- Obtain tissue diagnosis
- Avoidance of complications

symptomatic, RCCs should be considered for surgery, with the goals being to fenestrate and remove the cyst contents, relieve the mass effect, preserve or restore normal pituitary gland function, and avoid surgical complications (Table 10.2). In our experience, only approximately 40% of patients presenting with a RCC warrant surgery, and the remainder can be observed, given the small size of the cysts and lack of symptoms or signs.[11] In our recent study, cyst progression was noted on serial imaging in only 3% of patients who underwent conservative management.

Craniopharyngioma (see also Chapter 11)

Common presenting symptoms include vision loss, hypopituitarism (including diabetes insipidus [DI]), headaches, and cognitive impairment from hydrocephalus, and occasional hypothalamic dysfunction (including hyperphagia and obesity).[12,13] Surgery for craniopharyngiomas is often challenging because of their adherence to vital parasellar structures, including the optic apparatus, vessels of the circle of Willis, infundibulum, and hypothalamus (Fig. 10.5). As these tumors are generally radiosensitive, it is reasonable to attempt maximal safe removal, aim to preserve gland function (if intact preoperatively), and be willing to leave small tumor remnants for relatively neurologically intact patients, followed by adjuvant stereotactic radiotherapy to preserve endocrinological function (Table 10.2). More aggressive attempts at gross total resection with infundibulum removal may be considered for patients with multiple hormonal deficiencies, including DI. In some cases, an Ommaya reservoir may be inserted into a cystic component of the tumor, enabling access for serial cyst aspiration and, in rare cases, delivery of intratumoral chemotherapeutic agents (e.g., interferon-gamma or radioisotopes).[14] As most craniopharyngiomas are located in the retrochiasmal space, an endoscopic endonasal transtubercular approach is ideal for the majority of patients. Otherwise, a transcranial route may need to be considered.

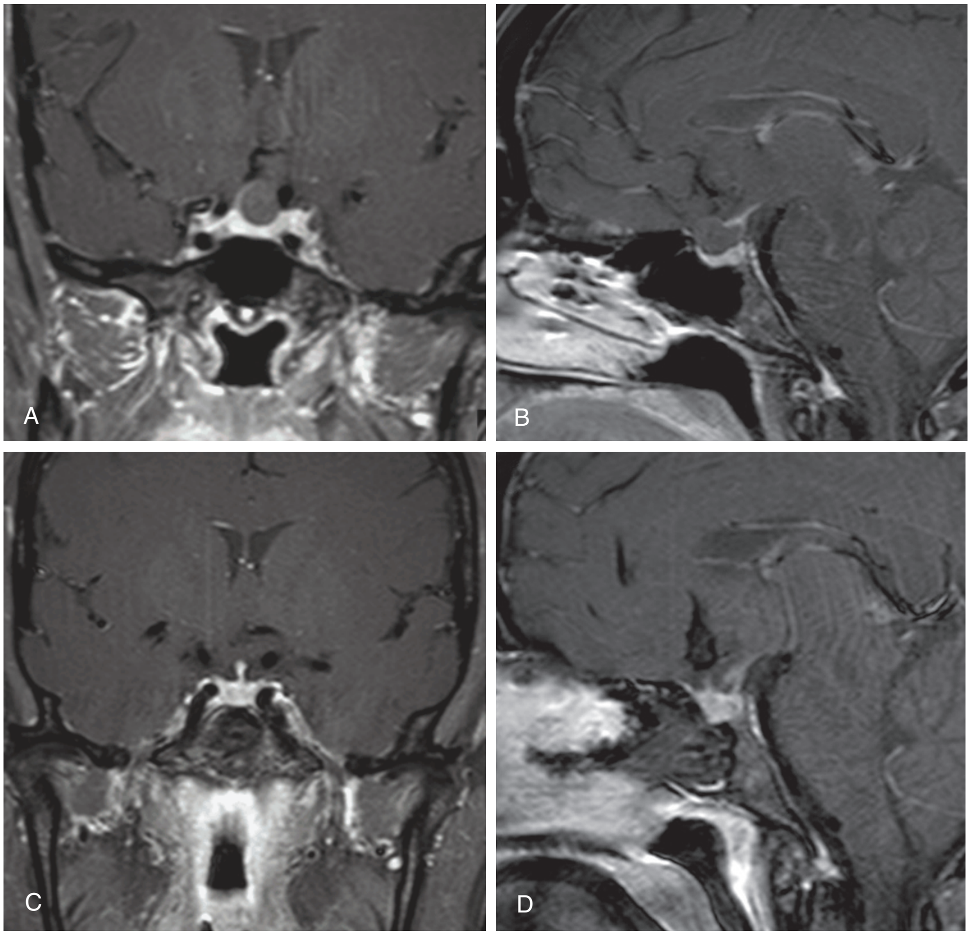

Fig. 10.4 Coronal (**A**) and sagittal (**B**) T1 with gadolinium magnetic resonance imaging (MRI) of an 83-year-old female presenting with intermittent hyponatremia, adrenal insufficiency, low insulin-like growth factor 1, and low gonadotropin levels. A large sellar and suprasellar nonenhancing lesion is seen between the adenohypophysis and neurohypophysis, consistent with a Rathke's cleft cyst. An endoscopic endonasal cyst fenestration was performed, with the postoperative day 1 MRI (**C, D**) showing gland reexpansion. She was placed on adrenal and thyroid replacement, with no further episodes of hyponatremia 2 years postoperatively.

Other Lesions

Although pituitary adenomas, RCCs, and craniopharyngiomas represent the majority of sellar pathologies, other pathologies are important to identify and treat appropriately. Several pathologies may mimic pituitary or sellar tumors, including carotid artery aneurysms, lymphocytic hypophysitis, hypothalamic hamartomas, and pituitary hyperplasia (e.g., primary hypothyroidism) (Fig. 10.6). It is critical to obtain all relevant imaging and consult a neuroradiologist in the context of the clinical presentation to avoid unnecessary surgery.

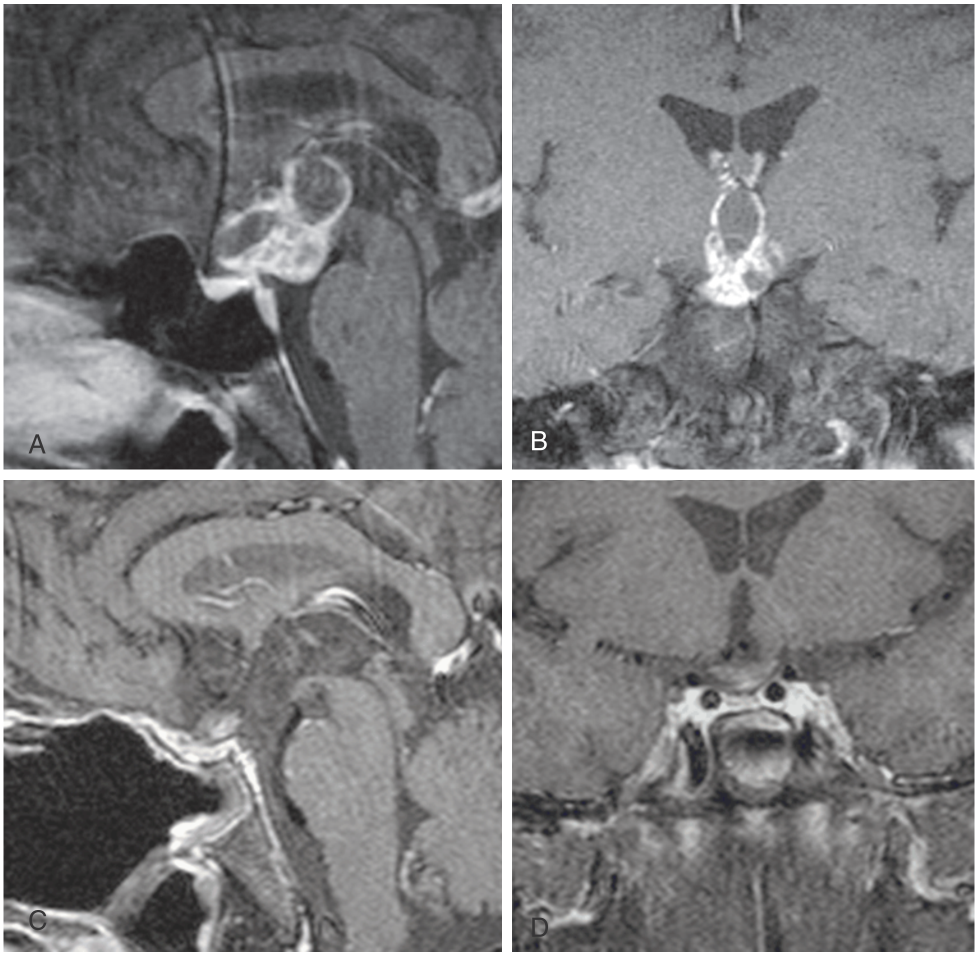

Fig. 10.5 Coronal (**A**) and sagittal (**B**) T1 with gadolinium magnetic resonance imaging (MRI) of a 52-year-old male presenting with persistent cold intolerance, weight gain, recent vision loss, and complete anterior and posterior pituitary failure. A large solid and cystic enhancing mass is seen in the suprasellar and retrochiasmal regions, consistent with craniopharyngioma. An endonasal endoscopic procedure was performed with gross total resection. Postoperative MRI 1 year later (**C, D**) demonstrates no residual or recurrent tumor, with intact nasoseptal flap used for the skull base reconstruction. His vision improved, and he remains on full pituitary hormone physiologic replacement.

PREOPERATIVE MANAGEMENT

Appropriate patient selection contributes directly to surgical outcomes. This includes not only medical fitness for surgery, but also a careful evaluation of any previous interventions, endocrinological status, individual anatomical characteristics, and the surgical goals. A multidisciplinary approach to patient selection is paramount, including assessments from neurosurgery, otolaryngology, endocrinology, radiology, neuroophthalmology, and anesthesiology.

KEY POINTS

- Indications for endoscopic endonasal pituitary surgery include relief of mass effect, hypersecreting endocrinopathy and pituitary apoplexy.

As such, patients diagnosed with a symptomatic pituitary adenoma, RCC, or craniopharyngioma should undergo (1) thorough clinical history and physical examination, (2) comprehensive pituitary hormonal assessment, (3) pituitary MRI with gadolinium (or computed tomography [CT] sellar imaging if MRI is not available or the patient has an MRI-incompatible implant such as a pacemaker), and (4) medical assessment for anesthesia safety, routine preoperative testing, and bloodwork. In patients with chiasmal or optic nerve compression (without or with visual complaints), an ophthalmology evaluation, preferably with a neuroophthalmologist, with visual field testing and ideally optical coherence tomography is obtained. Cardiac or pulmonary function testing may also be indicated depending upon a given patient's comorbidities. In particular, patients with advanced Cushing disease and acromegaly may have significant diabetes mellitus, hypertension, and cardiac dysfunction, including cardiomyopathy, arrhythmias, or valvular disease, warranting additional evaluation.[15] Preoperative panhypopituitarism, including DI, also warrants careful preoperative evaluation. Patients with acromegaly may also pose significant intraoperative challenges associated with difficult intubation from macroglossia, prognathism, and hypertrophy of laryngeal tissue.[16] An individualized approach is necessary to minimize perioperative complications.

Endocrine Status

Regardless of the symptomatology or pathology, all sellar/parasellar lesions that present with a consideration for surgery undergo a comprehensive evaluation of the hypothalamic-pituitary-adrenal axis. This includes assessment of the adenohypophysis (fasting morning cortisol and ACTH, GH, IGF-1, prolactin [PRL], TSH, total and/or free T4, luteinizing hormone, follicle-stimulating hormone, and testosterone/estrogen based on gender) and neurohypophysis (serum sodium, urine

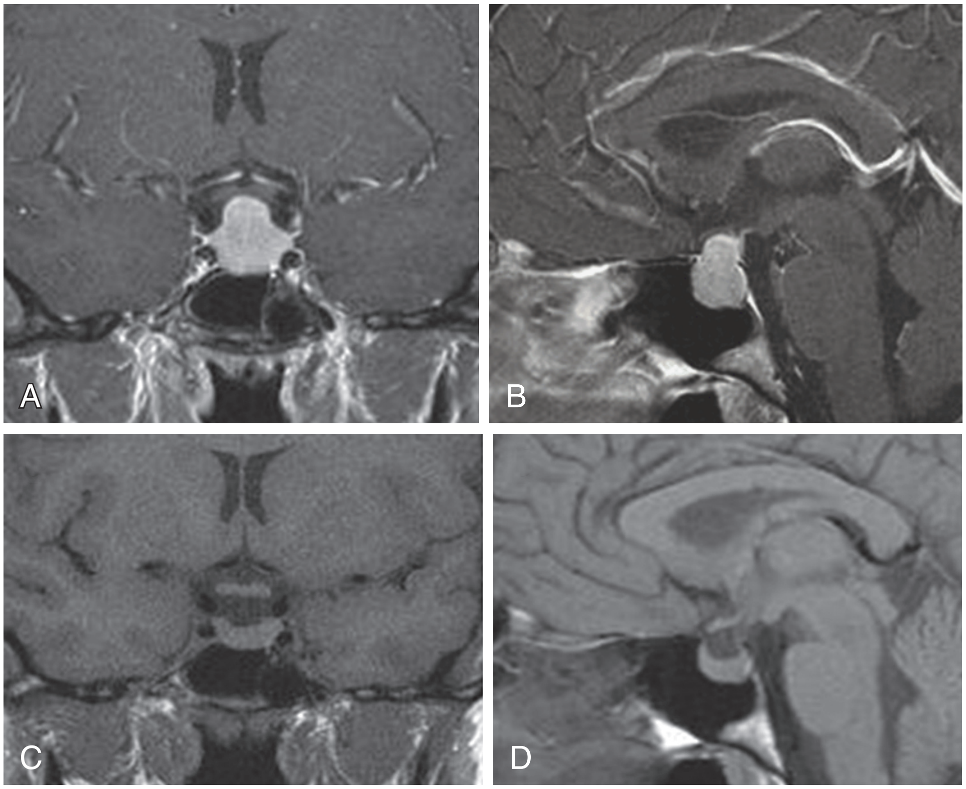

Fig. 10.6 Coronal (**A**) and sagittal (**B**) T1 with gadolinium-enhanced magnetic resonance imaging sequences of a 22-year-old female who presented with fatigue, headache, and galactorrhea and was found to have a serum prolactin level of 139 ng/mL. Preliminary diagnosis was of a pituitary adenoma, but during the workup she was found to have primary hypothyroidism with an elevated thyroid-stimulating hormone level of 1576 mIU/L and free T4 below 0.4 ng/dL. She was started on levothyroxine with normalization of serum free T4 level and resolution of pituitary hyperplasia (**C, D**).

osmolality/specific gravity, urine output). This provides a baseline endocrine status for subsequent postoperative assessments. There are specific endocrinological testing protocols to complete when evaluating patients suspected of having an endocrine-active adenoma, including Cushing disease, acromegaly, prolactinomas, and thyrotropinomas, which are described in other chapters in this text. However, of particular importance for surgery is to evaluate for hypocortisolemia, hypothyroidism, and DI, each of which, if not addressed preoperatively, can have a serious impact on the patient. Perioperative stress dosing with glucocorticoids is mandatory for patients with proven adrenal insufficiency. However, patients with either a normal adrenal axis or Cushing disease generally do not need preoperative glucocorticoids and instead can have cortisol levels monitored in the early postoperative period. Preoperative glucocorticoid administration interferes with the assessment of early biochemical remission in patients with Cushing disease.[17,18] If hypothyroidism is present, supplementation should not occur before corticosteroid supplementation so as to avoid an unsupported increase in metabolic rate leading to Addisonian shock.[19] DI may be treated with desmopressin (DDAVP) to correct hypernatremia, as described in Chapter 12. Chronic sodium aberrations from DI should be corrected no faster than 0.5 mEq/hour to avoid complications of cerebral edema.

Imaging Evaluation

All patients undergoing pituitary surgery should have a pituitary MRI with gadolinium and, in some instances, a thin-slice CT of the paranasal sinuses. The MRI is used primarily to identify the likely pathology, in correlation with the clinical and endocrinological findings, but also to determine the most appropriate surgical route and potential hazards or pitfalls. These include identification of the normal pituitary gland and infundibulum, relationship of critical nearby structures to the pathology, and extent of invasion into the CSs. An optimal MRI protocol includes T1, T1 with gadolinium, and T2 sequences with coronal and sagittal reformats. Fat saturation techniques are important to reduce the air artefact of the adjacent sphenoid sinus. A dynamic pituitary MRI study performs repeated T1 sequences after the administration of gadolinium and is helpful in identifying microadenomas because they tend to absorb the contrast later than normal pituitary tissue.[20] This is particularly helpful in patients with suspected Cushing disease (see also Chapter 7). A sequence with thin-slice thickness and spacing, such as magnetization prepared-rapid gradient echo, is helpful for registering an intraoperative neuronavigation systems. A dedicated thin-cut contrast-enhanced CT of the sella with coronal and sagittal reconstructions should be used in patients with contraindications to MRI.

The paranasal sinuses may be appreciated on a CT scan and are studied for nasal septum deviations, air cell anatomical variations, areas of bony dehiscence, the degree of sphenoid sinus pneumatization, and evidence of sellar expansion or bony changes indicating pathology diagnosis and chronicity. Together, MRI and CT allow for the planning of skull base reconstruction to minimize the risk of a postoperative CSF leak.

SURGICAL TECHNIQUE

Several surgical approaches to the pituitary gland and sellar region have been described. These are broadly divided into endonasal approaches and transcranial approaches. Once a patient has been deemed appropriate for surgery, careful consideration is given toward achieving the specific surgical goals (Table 10.2) and clearly understanding patient-specific anatomical factors. Today, the endoscopic endonasal approach is the predominant technique used for all sellar and parasellar tumors, and skull base neurosurgeons have largely transitioned from microscopic approaches.[6]

KEY POINTS

- Goals for endoscopic endonasal pituitary surgery include biochemical remission for hypersecreting endocrinopathies, relief of mass effect, preservation of normal pituitary gland function, effective closure of sella and/or skull base, obtaining a tissue diagnosis, and avoidance of complications.

In fact, graduates from many surgical training programs today are only trained in endoscopic techniques. Transcranial procedures are rarely indicated for pituitary adenomas and RCCs, but may be preferable in a significant minority of craniopharyngiomas based on anatomical factors, including location relative to the optic chiasm.

Endoscopic Endonasal Approach for Pituitary Adenoma, Rathke's Cleft Cyst, and Craniopharyngioma

The endonasal transsphenoidal approach provides a binostril direct trajectory to the sella with minimal tissue to transgress *en route*, passing through the nasal cavities and sphenoid sinus to reach the sella (see Fig. 10.1). There are many subtle variations to the procedure, but it is increasingly performed with both a neurosurgeon and otolaryngologist working together (Fig. 10.7). The major phases of the operation

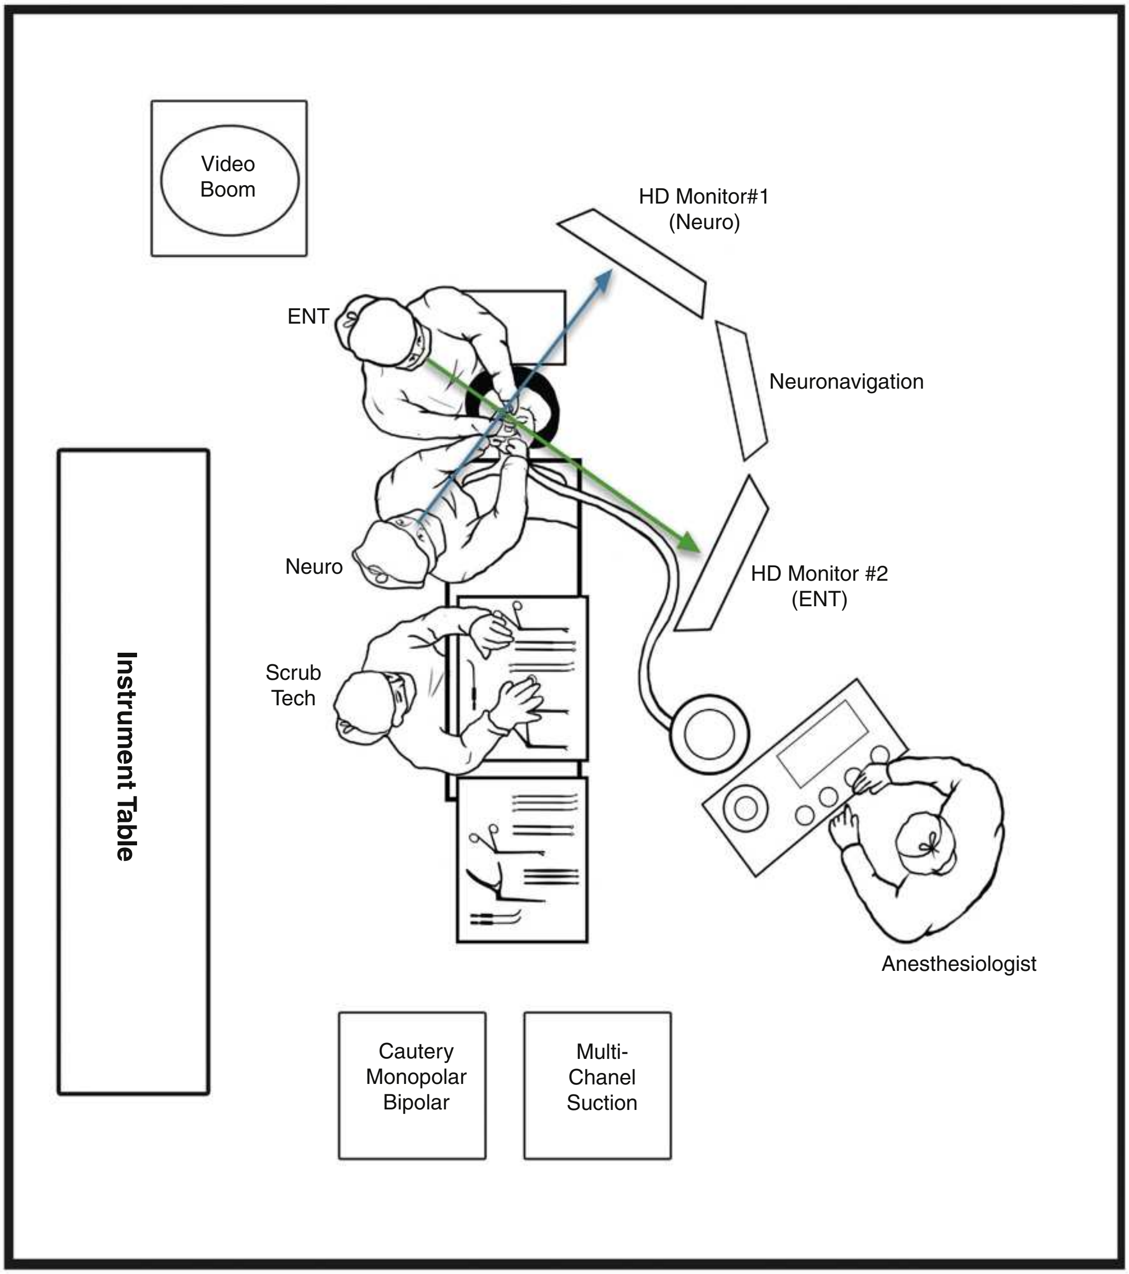

Fig. 10.7 Diagram of the typical operating room setup for endoscopic endonasal surgery. The procedure involves an otolaryngologist and neurosurgeon, both positioned on the patient's right side. Ergonomics are optimized by having an endoscope monitor positioned directly in front of each surgeon, as well as an arm rest for the otolaryngologist's left arm, holding the endoscope. *ENT,* Ear, nose and throat doctor; *HD,* high-definition.

include: (1) the sinonasal approach through the nasal cavities and sphenoid sinus, (2) the sellar exposure, (3) tumor or cyst removal, and (4) skull base reconstruction.

For all sellar and parasellar lesions, the patient is positioned supine on the operating room table with the head being slightly extended and laterally flexed for optimal surgical ergonomics. Most of the operation is performed with a 0-degree rigid 4-mm high-definition endoscope.

For the sinonasal approach, the nasal cavities are gently expanded through each nostril by out-fracturing, but not removing, the middle turbinates, then elevating bilateral nasoseptal mucosal rescue flaps. These strategically placed mucosal incisions allow exposure of the sphenoid keel bone while preserving bilateral posterior nasoseptal arteries and septal olfactory strips, thereby dramatically reducing the risk of early postoperative epistaxis and anosmia (Fig. 10.8).[21] The posterior aspect of the nasal septal bone is removed, and a wide sphenoidotomy is performed, connecting the two nasal corridors, allowing a binostril approach.

Next, removal of the sellar bone is performed with a combination of high-speed drills and rongeurs. This opening is tailored to the specific pathology based on preoperative imaging. A critical phase in this sellar exposure is localization of the parasellar ICAs using a combination of intraoperative neuronavigation and the Doppler probe (Fig. 10.9).

The sellar dura is then opened sharply, and the adenoma is localized and removed. In many cases, an attempt is made to use the adenoma pseudocapsule, which helps facilitate complete, *en bloc* removal. This technique, as well as minimizing traction on the gland, and making selective incisions in attenuated gland, can optimize adenoma access while minimizing risk of pituitary gland injury and postoperative hypopituitarism. For adenomas with likely CS invasion, or high suprasellar extension, visualization and accessing such tumor is performed with 30-degree and 45-degree endoscopes.

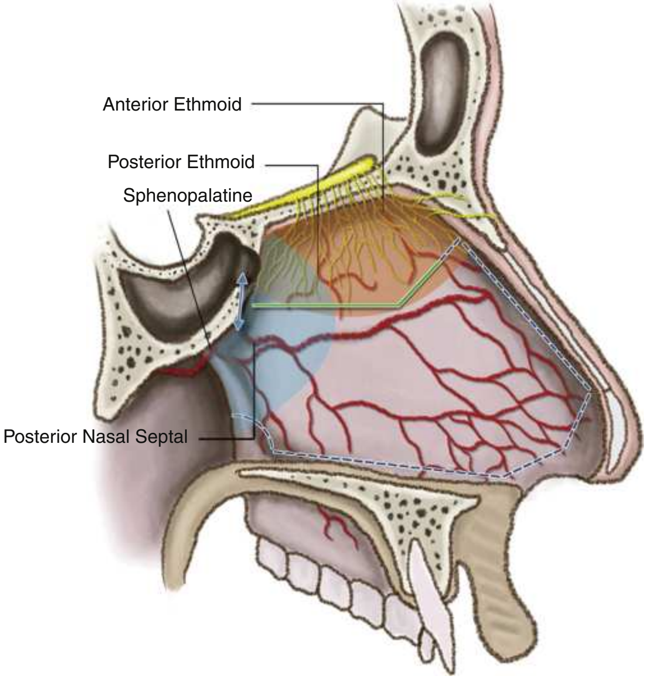

Fig. 10.8 Lateral view of the nasal septum depicting the mucosal cut made for elevating a nasoseptal rescue flap *(solid line)* during a standard endoscopic transsphenoidal surgery, preserving olfaction by sparing the septal olfactory strip, above which contains the olfactory nerve fibers. If needed, a nasoseptal flap may be harvested *(dashed line)*, supplied by the posterior septal artery of the sphenopalatine artery.

Finally, skull base reconstruction is performed to prevent postoperative CSF leak and meningitis. The specific repair protocol is dependent upon the grade of the CSF leak, with larger diaphragmatic defects warranting a more extensive repair.[22] An abdominal fat graft is used frequently during reconstruction to obliterate any sellar dead space, especially when an intraoperative CSF leak is identified. In our practice, nasoseptal flaps are used in only 2% to 3% of pituitary adenoma and RCC cases, but in the majority of craniopharyngioma operations.

Rathke's Cleft Cyst. The sellar approach to RCCs is generally identical to that of pituitary adenomas. Once the sellar dura is opened, a low vertical incision in the adenohypophysis is made to reach the cyst, given that most RCCs are located posterior to the adenohypophysis. The pituitary gland is resilient to such incisions, with generally no resultant increase in permanent hormonal dysfunction, as we recently demonstrated.[11,23] Cyst contents are then evacuated, and angulated endoscopes are used to gently explore the cyst lining to ensure complete removal. No attempt is made to strip the cyst lining, given that this maneuver can lead to permanent hypopituitarism. Skull base reconstruction then commences as described earlier.

Craniopharyngioma. For craniopharyngiomas, the extent of growth into the suprasellar cisterns dictates the extent of bony removal to access the lesion. In many cases, an extended transsellar, transtubercular approach is needed. The transsellar portion is the same as described previously, while the transtubercular component requires additional bone removal of the tuberculum sellae and a small portion of the planum sphenoidale. The dura and arachnoid are opened to expose the pituitary gland, infundibulum, and suprasellar cistern. In most instances of a retrochiasmal craniopharyngioma, tumor removal requires working through a narrow intracranial corridor above the pituitary gland and under the optic chiasm. This approach allows excellent visualization of the infundibulum and superior hypophyseal arteries, which require preservation if the gland and optic apparatus

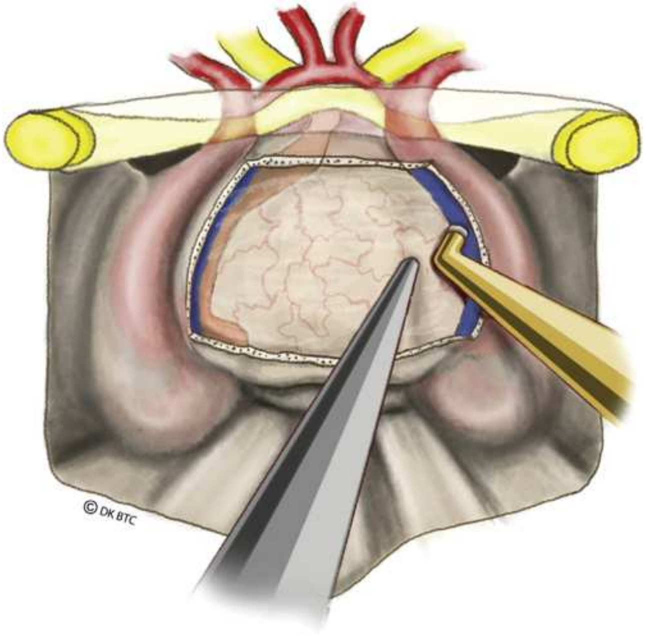

Fig. 10.9 To reduce the risk of vascular injury, the Doppler probe is used frequently during endoscopic endonasal surgery to identify the cavernous carotid arteries and other major vessels in real time during the approach to the sella and parasellar space. In this drawing, the left internal carotid artery is identified here during a transsphenoidal approach.

are to remain functional. After maximal safe tumor removal, skull base reconstruction proceeds, typically using an abdominal fat graft, collagen matrix, nasal septal bone graft, and a vascularized nasoseptal flap. This more extensive skull base repair is needed given the large diaphragmatic grade 3 CSF leak produced by the tumor removal itself.[22] Nasal sponges are generally placed for 5 to 6 days to ensure that the nasoseptal flap adheres well to the skull base. In our experience, lumbar drainage/CSF diversion is not necessary for such extended transsphenoidal approaches, although these are often used at other institutions.

ACUTE POSTOPERATIVE MANAGEMENT AND EARLY OBSERVATION POSTDISCHARGE

At our institution, most postoperative patients undergo a head CT in the recovery room before going to a step-down unit bed, to assess the skull base repair integrity. Patients with pituitary adenomas or RCCs generally go to a step-down unit and, length of stay is typically 1 to 2 nights. Patients with a craniopharyngioma or a giant adenoma with large supradiaphragmatic extension will typically spend one night in the intensive care unit, then another night or two in the step-down unit. A sellar MRI is performed on postoperative day 1. Perioperative antibiotics and nasal care are administered, with varying protocols employed based on whether nasal sponges were inserted during surgery.

After discharge from hospital, patients will have an outpatient assessment of their serum sodium level on postoperative day 5 to 7 to rule out delayed hyponatremia, as well as serum cortisol, ACTH, and any other relevant hormones (e.g., serum PRL for prolactinomas). Follow-up appointments will be arranged with otolaryngology on postoperative day 5 or 10 (depending on the presence or absence of nasal sponges), neurosurgery on postoperative day 10, and endocrinology, neuroophthalmology, neurooncology, and others as needed. A pituitary MRI is generally performed approximately 3 months after surgery, with subsequent imaging surveillance based on pathology and residual disease.

Endocrinological monitoring in the acute postoperative phase is focused on three potential events: (1) DI and sodium fluctuations (syndrome of inappropriate antidiuretic hormone [SIADH]), (2) acute adrenal insufficiency, and (3) early remission in endocrine-active adenomas.

KEY POINTS

- Endocrinological monitoring in the acute postoperative phase is focused on three potential events: (1) diabetes insipidus and sodium fluctuations (syndrome of inappropriate antidiuretic hormone), (2) acute adrenal insufficiency, and (3) early remission in endocrine-active adenomas.

Diabetes Insipidus

All patients are closely monitored for postoperative DI with hourly recordings of fluid intake and output (if a Foley catheter is in place) or with each void. An output of more than 400 mL in a single hour or greater than 200 mL/hour when averaged out between voids prompts an assessment of serum sodium and urine specific gravity. Patients are encouraged to drink to thirst. DDAVP is administered intravenously if the specific gravity is below 1.005 and the patient is hypernatremic or unable to maintain oral fluid intake. DI may be transient or permanent, which may ensue from a triphasic response. The incidence of transient DI after transsphenoidal surgery is highly variable in the literature (between 1% and 60%, and typically around 20%) and often occurs within the first 5 days after surgery, resolving by postoperative day 11 in most cases.[24,25] Persistent DI (greater than 3 months) has been reported in up to 10% (ranging from 0% to 3.8% in our series), with risk factors including increased tumor size and surgery for RCCs or craniopharyngiomas.[23,24,26,27]

Syndrome of Inappropriate Antidiuretic Hormone

SIADH is a relatively common occurrence after pituitary surgery, with a reported incidence of between 2% and 35%.[28] The peak time of onset is on postoperative days 7 and 8, but can occur anytime between days 4 and 12.[29] While the pathogenesis remains uncertain, a recent study by Burke et al. compared a prophylactic fluid restriction of 1 L/day for 1 week after discharge from hospital to a retrospective control cohort without fluid restriction. They found that none of the 203 patients in the fluid restriction cohort required readmission for hyponatremia, compared with 3.41% of the 585 in the control cohort.[30] We have implemented this into our practice with success. Postoperatively, we obtain a baseline serum sodium level, followed by a repeat level on postoperative day 5, at around the time of peak incidence. We ensure that we educate the patient of the symptoms of hyponatremia, including headache, confusion, nausea, vomiting, fatigue, and muscle cramps. Should hyponatremia occur, an evaluation for adrenal insufficiency and hypothyroidism may be necessary, based on the clinical scenario. No consistent risk factors have been identified for the onset of delayed hyponatremia, but some studies have suggested increased tumor size, female gender, and advanced age to be possible risk factors.[31-39]

Early Remission

Patients with acromegaly, Cushing disease, prolactinomas, and thyrotropinomas are assessed for early biochemical remission while in hospital.[18,27,40] For acromegaly, postoperative day (POD) 1 and 2 morning GH levels are drawn, and early remission is a POD 1 or 2 GH level of 1 ng/mL or less and a subsequent normal sex- and age-adjusted IGF-1 at least 3 months after surgery. Patients with Cushing disease have serum cortisol and ACTH levels monitored at 8-hour intervals. Early remission is defined by a POD 1 or 2 morning cortisol level less than 5 g/dL and needing cortisol replacement for at least 3 months postsurgery. Stress-dose replacement hydrocortisone is administered in hospital once this cortisol drop occurs, followed by a taper to physiological replacement, typically within 3 to 4 days of surgery which is then maintained and slowly tapered off over 6 to 12 months postsurgery. For prolactinomas, early remission is defined as a POD 1 or 2 morning PRL level less than 10 ng/dL and normal serum PRL level (<20 ng/mL for men and <25 ng/mL for women) at least 3 months postsurgery without dopamine-agonist therapy. For thyrotropinomas, remission is defined as a normal TSH and free T4 at least 3 months postsurgery.

OUTCOMES AFTER TRANSSPHENOIDAL PITUITARY ADENOMA SURGERY

At high-volume pituitary centers with experienced surgeons, pituitary adenoma surgery generally has a high success rate in terms of endocrine remission rates, preservation of hormonal function, visual recovery, and headache resolution, with low complication rates.

KEY POINTS

- At high-volume pituitary centers with experienced surgeons, pituitary adenoma surgery generally has a high success rate in terms of endocrine remission rates, preservation of hormonal function, visual recovery, and headache resolution, with low complication rates.

Improvement in visual acuity and visual fields is typically seen in 75% to 90% of patients presenting with bitemporal or monocular vision loss associated with an adenoma. Similarly, headache resolution occurs in 70% to 90% of patients who present with preoperative headache.[27,41,42] As shown in Table 10.3, complications rates in recent large retrospective series of pituitary adenoma patients undergoing

N – number of patients; *EOR* – extent of resection; *LOS* – length of stay; *CSF* – cerebrospinal fluid; *R* – retrospective; *Pr* – prospective; *NR* – not reported; *GTR* – gross total resection; *NTR* – near total resection; *A* – anterior; *P* – posterior; *EndoR* – endocrine remission *CND* - cranial nerve deficit endonasal endoscopic surgery are quite low, ranging from 0% to 2% for carotid artery injury, visual worsening, meningitis, and sellar hematoma; the rate of new hypopituitarism typically is under 8% to 10%.[43-50]

MAJOR COMPLICATIONS

Permanent Hypopituitarism

New permanent anterior and posterior hypopituitarism after pituitary adenoma removal is generally low in experienced hands at high-volume centers, ranging on average from 2% to 7%, and, as we have demonstrated, is most dependent upon tumor size.[27,48,52-59] For adenomas under 2 cm, the risk of new hypopituitarism is typically 1% to 5%, but with adenomas over 3 cm (including giant adenomas), the rate may range from 10% to 15%.[60] Similarly, the rate for new hypopituitarism for RCC is also quite low, ranging from 0% to 4%, and in our recent series of 36 patients, none had new hypopituitarism.[11] The rate of new permanent hypopituitarism is significantly higher for craniopharyngiomas and giant pituitary adenomas, with reported incidences of up to 58%.[26,61,62] We routinely obtain postoperative morning serum cortisol and ACTH levels to monitor for hypocortisolemia, while other hormone levels are checked at a later date as an outpatient as needed. Important surgical concepts that may reduce the risk of anterior hypopituitarism include preoperative identification of the normal gland on MRI, respecting the tumor pseudocapsule (when present), avoiding undue traction to the gland with gentle manipulation, and using selective gland incisions to reduce gland traction and manipulation.

Cerebrospinal Fluid Leak and Meningitis

Avoiding postoperative CSF leaks remains a key goal in transsphenoidal adenoma surgery, and the incidence in most large recent series is under 5%. In our recent large series of endoscopic endonasal skull base repair including 362 pituitary cases, the postoperative CSF leak rate was 1.4%, and the meningitis rate was 1.1%.[22] Our experience, and that of others, suggests that a graded repair protocol based on the size of the skull base defect is highly effective for most patients. However, patients with a higher body mass index (generally >30) are at increased risk of postoperative CSF leak, and we have a low threshold to place nasal packing as a temporary buttress in such patients. Additionally, we place all patients with an intraoperative leak (grade 1, 2, or 3) on acetazolamide 250 mg by mouth every 8 hours for 2 days. Should a postoperative leak be discovered while the patient is in hospital or after discharge, in most instances reoperating to revise the repair is indicated, although in some patients temporary CSF diversion with a lumbar drain is reasonable.[22] This is assessed via a "tip test" or "tilt test", where the patient leans forward to observe for clear nasal rhinorrhea. The fluid is assessed for βeta-2 transferrin, which is very specific for CSF. The separation of blood from the draining fluid on gauze or paper, known as the halo sign, has been shown to be neither sensitive nor specific for CSF.[63] Confirmatory tests may be necessary in some occult cases of persistent postoperative CSF rhinorrhea, including CT myelogram or nuclear scintigraphy myelogram with nasal pledget radionucleotide detection.

Should patients develop signs and symptoms of meningitis postoperatively, such as nuchal rigidity, headache, decreased level of consciousness, photophobia, and fever, a timely workup should commence. This includes serum white blood cell count, erythrocyte sedimentation rate, C-reactive protein, electrolytes, and blood culture, as well as a lumbar puncture to evaluate for cell counts, protein, glucose, gram stain, and culture. MRI with gadolinium of the brain should be obtained to assess for potential infection location, as well as hydrocephalus, which may need to be treated with either an external ventricular drain or a lumbar drain. Ideally, broad-spectrum antibiotics should be administered once serum and CSF samples have been collected for culture, but this should not be delayed. Current guidelines suggest the use of vancomycin and a third- or fourth-generation cephalosporin for adequate CSF penetration.[64] Once an organism is isolated, the antibiotics may be tailored to the susceptibility profile of the pathogen. Duration of antibiotic use is usually 14 days, or 21 days for gram-negative bacilli. In some cases, cultures may return negative, suggesting possible aseptic meningitis. Clinical acumen must be relied upon to decide whether or not to continue antibiotics, which takes into account the clinical scenario, CSF analysis, and imaging findings.

Cranial Nerve Injury

Although an uncommon complication, the optic nerves and chiasm, abducens, oculomotor, and trochlear cranial nerves may be at risk during surgery, especially for tumors such as invasive pituitary adenomas and craniopharyngiomas that may invade the CSs or extend superiorly beyond the sellar diaphragm toward the optic apparatus.[65,66] Every artery of the circle of Willis supplies small branches to the optic apparatus. Most relevant to endoscopic endonasal pituitary surgery are the superior hypophyseal and anterior cerebral arteries, which must be meticulously dissected to prevent visual pathway impairments. Craniopharyngiomas frequently extend through the suprasellar cisterns and may be adherent to these arteries. These challenging tumors are associated with a 2% to 8% risk of new or worsening vision deficit.[61,67-70] For routine pituitary adenomas and RCCs, new or worsened diplopia from a cranial neuropathy occurs in less than 1% of patients.[11] The risk of cranial neuropathy, especially abducens, oculomotor, and trochlear nerves, increases as the pathology and surgical corridor extend further laterally into the CSs or inferiorly along the brainstem, requiring a transclival approach.[71] For such cases, intraoperative cranial nerve monitoring should be used.

Postoperative Intrasellar Hematoma

As with any surgical procedure, meticulous hemostasis is required to minimize the risk of hematoma formation. In pituitary surgery, the risk is greatly increased when residual adenoma remains. Hematoma formation may result in postoperative headache, cranial neuropathy, vision loss, or hydrocephalus. Patients with a coagulopathy are especially prone to hematoma formation and should be optimized medically before surgery. The presence of a hematoma in some cases warrants a return to the operating room for evacuation, particularly if large or symptomatic.

Internal Carotid Artery Injury

Injury to the ICA is a serious, but fortunately rare, complication, and in most large series occurs in less than 1% of patients.[10,43-46] The segment within the CS is the most common site of injury, with a reported injury rate of 1.1%.[72,73] Catastrophic bleeding may occur, risking stroke or death, necessitating immediate and definitive action to mitigate. Once the bleeding has been stabilized, the procedure is aborted, and the patient is brought to the angiography suite for evaluation of arterial injury and/or pseudoaneurysm formation. In many cases either a covered stent or flow-diverting stent is used, with an approximately 90% success rate.[74] At our institution, we have implemented a "carotid injury timeout" in conjunction with a standard operative timeout for high-risk procedures. These include patients with previous surgery, previous radiation, or invasive parasellar tumors that incorporate a segment of the ICA. Additional equipment is made available in the room to deal with a carotid artery injury, including essential instruments, backup equipment, medications, and crossmatched blood. The neurointerventional team is notified before the operation. With the use of an intraoperative navigation system and a Doppler probe, the incidence of ICA injury is dramatically reduced.[75]

TABLE 10.4 **Remission Rates for Pituitary Adenomas After Endoscopic Endonasal Resection**

	SURGICAL REMISSION RATE (%)	
Tumor Type	**Microadenoma**	**Macroadenoma**
Acromegaly	70–90	50–75
Cushing Disease	65–95	55–95
Prolactinoma	80–95	40–90
Thyrotropinoma (Thyroid-Stimulating Hormone-Secreting)	60–90	
Endocrine-Inactive	55–90	

RESECTION AND REMISSION RATES

Pituitary Adenoma

Overall rates of gross total resection for endocrine-inactive adenomas range from approximately 55% to 90% (Table 10.4).[76-79] Risk factors for near-total or subtotal removal include CS invasion, supradiaphragmatic extension, giant adenoma (≥4 cm in maximal diameter), and prior surgery. In these cases, the surgical goal is still maximal safe removal with pituitary gland and optic apparatus decompression. Serial imaging must be performed as growth of the residual tumor has been observed in as many as half of patients after 3 years[80] (see also Chapter 8).

Similar to endocrine-inactive adenomas, for endocrine-active adenomas, remission rates are significantly higher for microadenomas associated with acromegaly, Cushing disease, prolactinomas, and TSH-secreting adenomas than for macroadenomas. CS invasion is the most important factor precluding endocrine remission, even with the use of endoscopy. As described in other chapters, for large macroadenomas or invasive adenomas that cannot be completely removed, adjuvant therapies including medical therapies and/or radiosurgery or stereotactic radiotherapy may be needed to achieve remission and to halt tumor progression.

Rathke's Cleft Cyst

Recent surgical series of RCCs report high rates of improvement of headaches (71%–100%), visual disturbances (64%–100%), and hyperprolactinemia (67%–100%) but less successful rates of recovery of pituitary gland function, both anterior (18%–70%) and posterior (0%–50%).[11,81-83] A recent metaanalysis found an overall recurrence rate for these lesions of 12.5%, with recent series reporting recurrence rates from 0% to 21%.[84-86] Squamous metaplasia found on histopathological examination has been shown to increase the rate of recurrence.[34,82,86] Gross total removal of the cyst wall does not improve recurrence rates compared with cyst drainage with fenestration, but does appear to increase the rates of new endocrinopathy. The rate of new hypopituitarism has been reported at 0% to 67% in various series, but is typically around 5% to 15% when utilizing the cyst fenestration approach.[84-86] We do not remove the cyst wall, and have had no patients develop new permanent DI or hypopituitarism, and have noted a symptomatic recurrence rate of only 8%.[11] We have also noted 100% of patients with visual loss recovered, and over 80% of patients had an improvement in headache and endocrinopathy.

Craniopharyngioma (see also Chapter 11)

Given their invasiveness to surrounding structures, subtotal removal of craniopharyngiomas is common, and most will require radiosurgery or stereotactic radiotherapy for treatment of residual or recurrent tumor. Recent endoscopic series report complete removal rates ranging from 37% to 75%.[61,67,68] Improvement of vision is high, ranging from 75% to 86% of patients. Given the intimate association of the tumor with the infundibulum, the rate of new or worsened hypopituitarism of the anterior gland is high, ranging from 38% to 47%, and the rate of new DI ranges from 42% to 48%. Other complications of craniopharyngioma surgery include worsened vision (2%–2.5%), CSF leak (3.8%–23.4%), and hyperphagia related to hypothalamic injury, which can occur in a significant minority of adult patients.[61,67,68,87]

An important and somewhat recent understanding in managing craniopharyngiomas is that of the two histological subtypes, adamantinomatous and papillary; while the former is much more common, the latter is nearly always associated with a BRAF V600E missense mutation. Several clinical trials are currently underway examining the efficacy of BRAF inhibitors and mitogen-activated protein kinase inhibitors in recurrent papillary craniopharyngiomas. Currently, there are only case reports and small case series published, but randomized control trials are underway.[88] We have incorporated BRAF therapy at our institution for select papillary craniopharyngioma patients, with good preliminary outcomes.

PITUITARY CENTERS OF EXCELLENCE

Pituitary and related sellar tumors present significant diagnostic and therapeutic challenges to endocrinologists, neurosurgeons, and other involved subspecialties, such as radiation oncologists and neuropathologists. Given their complexity, it is increasingly accepted that, for most patients with a pituitary tumor, optimal treatment is achieved with a multidisciplinary approach from an integrated group of highly experienced specialists.

KEY POINTS

- Pituitary and related sellar tumors present significant diagnostic and therapeutic challenges, and optimal treatment is achieved with a multidisciplinary approach from an integrated group of highly experienced specialists in a Pituitary Center of Excellence.

This concept of *pituitary centers of excellence* (COE) has been promoted for over two decades, including in an article published in 2012 in *Neurosurgery*.[7] In that article we stressed the complexity of managing pituitary tumor patients in terms of both achieving the correct diagnosis and delivering optimal management, and the need for a team approach (Fig. 10.10). We also showed data on the relationship between surgical experience to clinical outcomes and drew parallels from other surgical subspecialties on the importance of experience. In particular, we proposed that a pituitary COE "should fulfill 3 key missions: (1) provide comprehensive care and support to patients with pituitary disorders; (2) provide residency training, fellowship training, and/or continuing medical education in the management of pituitary and neuroendocrine disease; and (3) contribute to research in pituitary disorders."[7] Since 2012, multiple other publications have supported this concept of pituitary COEs, including a 2017 *Pituitary Society* Statement paper outlining their proposed criteria to define a pituitary COE.[89] These criteria outline the ideal training and experience required by neurosurgeons and endocrinologists and emphasized the establishment of a group of expert supporting units in neuroradiology, neuropathology, radiation oncology, neurooncology, neuroophthalmology, and specialized clinical and research nursing. Similar to our original paper in 2012, the *Pituitary Society* also proposed that pituitary COEs should contribute scientific research for the advancement of pituitary

medicine through clinical trials, peer-reviewed publications, residency and fellowship training, and pituitary-related conferences.

CONCLUSION

Pituitary surgery has evolved substantially since its inception over a century ago. Many advances since then have helped transform the care and outcomes of patients diagnosed with pituitary adenomas, RCCs, craniopharyngiomas, and other pathologies. The endoscope is one such advancement that has become the predominant visualization technique for endonasal pituitary and skull base surgery and has largely supplanted the operating microscope. With an increasing emphasis on a multidisciplinary approach and careful perioperative neuroendocrine monitoring, modern pituitary surgery has well-defined indications and goals that, over recent decades, have resulted in incrementally improved resection and remission rates, visual recovery, and gland preservation rates, as well as reduced incidence of complications. Collectively, these advances, along with close collaboration between neurosurgeons, endocrinologists, and other specialists, have dramatically advanced the field of pituitary medicine.

TYPES OF PARASELLAR MASSES

Various types of nonadenomatous lesions can be detected in the parasellar area (Table 11.1). The most common are craniopharyngiomas, Rathke's cleft cysts, and meningiomas. They generally present with mass effects to surrounding structures, or they may be incidentally found. Their management depends on their etiology, location, presenting manifestations, and potential for aggressive/malignant behavior. Other neoplastic lesions are much more rare; inflammatory lesions will not be discussed further in this chapter.

CRANIOPHARYNGIOMAS

Epidemiology

Craniopharyngiomas account for 2% to 5% of all primary intracranial neoplasms (up to 15% of intracranial tumors diagnosed in childhood).[1] Their annual incidence is around 0.18 cases per 100,000 population[2] and can be detected at any age, including the prenatal and neonatal periods.[3] A bimodal age distribution with a peak incidence rates at ages 5 to 14 years and 50 to 74 years has been described,[2,4] the pathophysiological significance of which is uncertain. No sex differences have been confirmed.[4,5]

Pathology

Craniopharyngiomas are World Health Organization (WHO) grade I epithelial tumors arising along the path of the craniopharyngeal duct (the canal connecting the stomodeal ectoderm with the evaginated Rathke's pouch). Malignant transformation has been rarely reported and is possibly triggered by previous irradiation.[1] Histologically, there are two subtypes, the adamantinomatous and the papillary.[1,6]

The adamantinomatous is the most common subtype and is diagnosed at any age. Macroscopically, it consists of cystic and/or solid components, necrotic debris, fibrous tissue, and calcification. The cystic fluid ranges from "machinery oil" to shimmering cholesterol-laden fluid consisting of desquamated squamous epithelial cells, rich in membrane lipids and cytoskeleton keratin. Their margins can be sharp and irregular, often merging into a peripheral zone of dense reactive gliosis in the surrounding brain tissue. The epithelium is typically composed of three layers of cells: a distinct palisaded basal layer; an intermediate layer of variable thickness composed of loose aggregates of stellate cells (termed "stellate reticulum"); and a top layer facing into the cyst lumen with abruptly enlarged, flattened, and keratinized to flat plate-like squamous cells. The flat squames are desquamated and form nodules of "wet" keratin which often show heavy calcification. The presence of the typical adamantinomatous epithelium or of the "wet" keratin nodules alone are diagnostic for this variant.[1]

The papillary subtype has been almost exclusively described in adults. It consists of mature squamous epithelium forming pseudopapillae and of an anastomosing fibrovascular stroma with membranous beta-catenin immunoreactivity only (in contrast to adamantinomatous, which can also demonstrate nuclear immunopositivity for beta-catenin). The differential diagnosis between a papillary craniopharyngioma and a Rathke's cleft cyst may be difficult; in such cases, absence of a solid component and the presence of extensive ciliation and/or mucin production are suggestive of Rathke's.[1,6]

Pathogenesis

Beta-catenin mutations in exon 3 have been identified in the adamantinomatous subtype. This exon encodes the degradation targeting box of beta-catenin, and the mutant form is resistant to degradation leading to accumulation of nuclear beta-catenin protein (a transcriptional activator of the Wnt signaling pathway). Strong beta-catenin expression has been shown in the adamantinomatous subtype, indicating reactivation of the Wnt signaling pathway and subsequent deregulation of several downstream pathways.[7-9]

TABLE 11.1 Types of Nonadenomatous Parasellar Masses

Tumoral Lesions	Craniopharyngioma Meningioma Chordoma Glioma Langerhans cell histiocytosis Schwannoma Neurofibroma Lymphoma Germ cell tumor Metastasis Chondrosarcoma Paraganglioma Hemangiopericytoma Hamartoma Lipoma Tumors of posterior pituitary
Cystic lesions	Rathke's cleft cyst Epidermoid cyst Dermoid cyst Arachnoid cyst Sphenoid sinus mucocele
Vascular	Aneurysms Cavernous hemangioma Cavernous sinus thrombosis Carotid cavernous fistula
Inflammatory/infectious	Sarcoidosis Wegener's granulomatosis Tolosa–Hunt syndrome Tuberculosis Abscess

In the papillary subtype, activating mutations in *BRAF* (V600E) have been detected (in 81%–100% of cases, depending on the sequencing method used), and expression of the mutant protein has been confirmed by immunohistochemistry implicating activation of the RAS/RAF/MEK/ERK pathway.[8]

Gains or losses of large chromosomal regions are rare in craniopharyngiomas, and the two pathological subtypes have different epigenomic and transcriptomic signatures.[8]

KEY POINTS

- Craniopharyngiomas are very rare tumors (annual incidence around 0.18 cases per 100,000 population) and comprise two distinct pathological subtypes: adamantinomatous (often carrying *beta-catenin* mutations) and papillary [characterized by *BRAF* (V600E) mutations]

Imaging Features

Most craniopharyngiomas are located in the sellar/parasellar region and the majority of them (94%–95%) have a suprasellar component at the time of detection. In terms of consistency, they can be purely or predominantly cystic, purely or predominantly solid, or mixed. Rare locations of these tumors that have been reported are the nasopharynx, the paranasal area, the sphenoid bone, the ethmoid sinus, the intrachiasmatic area, the temporal lobe, the pineal gland, the posterior cranial fossa, the cerebellopontine angle, the midportion of the midbrain, or within the third ventricle.[1]

On computed tomography (CT), they are usually of mixed attenuation; the cyst fluid has low density, and the contrast medium enhances any solid portion, including the cyst capsule. This imaging modality is helpful in identifying calcification.[1] On magnetic resonance imaging (MRI), the appearances depend on the proportion of the solid and cystic components, the content of the cyst(s) (cholesterol, keratin, hemorrhage), and the degree of tumor calcification (Fig. 11.1). On precontrast T1-weighted images, a solid lesion appears as

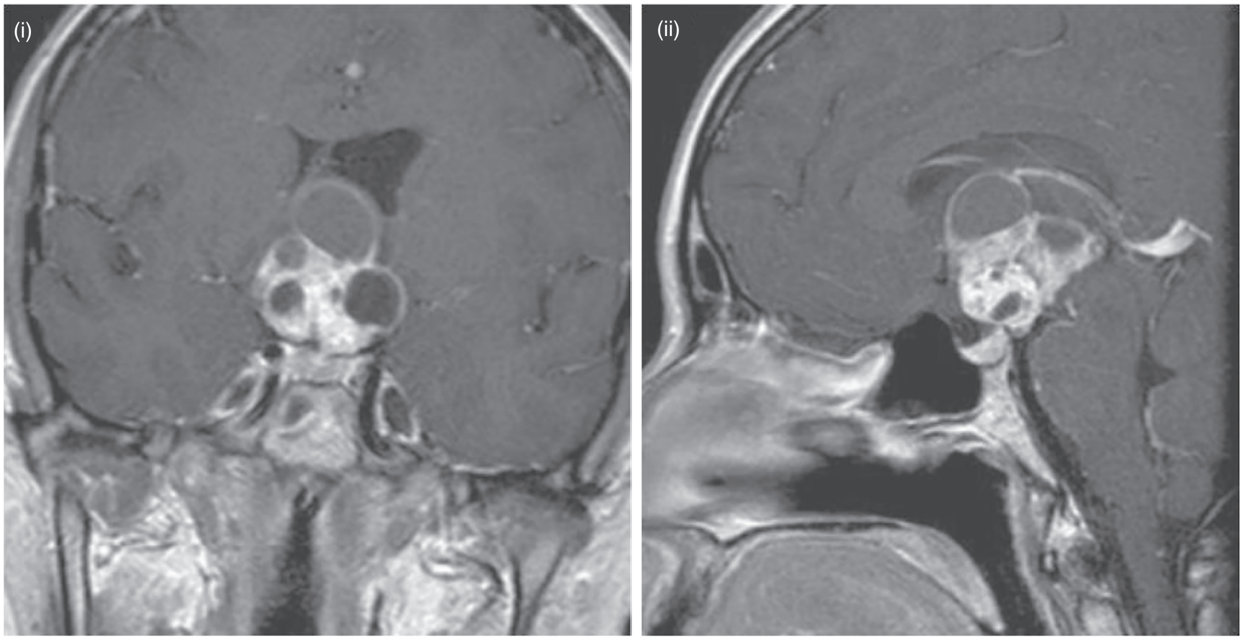

Fig. 11.1 Magnetic resonance imaging of craniopharyngioma. Coronal (i) and sagittal (ii) T1-weighted postgadolinium images with lobulated shape and mixed solid and cystic characteristics. Peripheral contrast-enhancing rim of the cystic components are evident. (From Trifanescu R, Ansorge O, Wass JA, et al. Rathke's cleft cysts. *Clin Endocrinol (Oxf)*. 2012;76:151–160.)

TABLE 11.2 Presenting Clinical Features in Children and Adults With Craniopharyngioma

	Children	Adults	Total
Headaches	78%	56%	64%
Menstrual disorders		57%	
Visual field defects	46%	60%	55%
Decreased visual acuity	39%	40%	39%
Nausea/vomiting	54%	26%	35%
Growth failure	32%		
Poor energy	22%	32%	29%
Impaired sexual function		28%	
Impaired secondary sexual characteristics (patients aged ≥13 years)			24%
Lethargy	17%	26%	23%
Other cranial nerves palsies	27%	9%	15%
Polyuria/polydipsia	15%	15%	15%
Papilledema	29%	6%	14%
Cognitive impairment (memory, concentration)	10%	17%	14%
Anorexia/weight loss	20%	8%	12%
Optic atrophy	5%	14%	10%
Hyperphagia/excessive weight gain	5%	13%	10%
Psychiatric symptoms/change in behavior	10%	8%	8%
Somnolence	5%	10%	8%
Galactorrhea		8%	
Decreased consciousness/coma	10%	4%	6%
Cold intolerance	0%	8%	5%
Unsteadiness/ataxia	7%	3%	4%
Hemiparesis	7%	1%	3%
Blindness	3%	3%	3%
Meningitis	0%	3%	2%

(From Karavitaki N, Brufani C, Warner JT, et al. Craniopharyngiomas in children and adults: systematic analysis of 121 cases with long-term follow-up. *Clin Endocrinol (Oxf)*. 2005;62:397–409.)

iso- or hypointense relative to the brain and enhances after gadolinium administration; on T2-weighted images, craniopharyngiomas are usually of mixed hypo- or hyperintensity. Cystic parts are usually hypointense on T1- and hyperintense on T2-weighted sequences, and a thin peripheral contrast-enhancing rim of the cyst can be shown on T1-weighted images. Protein, cholesterol, and methemoglobin relate with high signal on T1-weighted sections, while very concentrated protein and various blood products can be associated with low T2-weighted signal.[1]

The differential diagnosis on imaging includes a number of sellar or parasellar lesions, including Rathke's cleft cyst, dermoid cyst, epidermoid cyst, pituitary adenoma, germinoma, hamartoma, suprasellar aneurysm, arachnoid cyst, suprasellar abscess, glioma, meningioma, sarcoidosis, tuberculosis, and Langerhans cell histiocytosis (LCH). Differentiation from a Rathke's cleft cyst (typically small, round, purely cystic lesions lacking calcification) can occasionally be challenging.[1,10]

CLINICAL MANIFESTATIONS AND PITUITARY FUNCTION AT PRESENTATION

The presenting manifestations are attributed to pressure effects on surrounding structures including the visual pathways, brain parenchyma, ventricular system, major blood vessels, and the hypothalamopituitary system.[10-12] Their severity depends on the location, size, and growth potential of the tumor, and the duration of the symptoms until diagnosis ranges from 1 week to 372 months.[1] The main presenting clinical features (neurological, visual, hypothalamopituitary) are shown in Table 11.2. Headaches, nausea/vomiting, visual disturbances, growth failure (in children), and hypogonadism (in adults) are the most frequently reported. Particularly in childhood-onset craniopharyngioma, a reduced growth rate is already evident in early infancy, whereas weight gain tends to present later and predicts obesity.[13] Various rates of hypothalamopituitary dysfunction have been reported, with growth hormone (GH) deficiency diagnosed in 35% to 100% of the evaluated patients, follicle-stimulating hormone (FSH)/luteinizing hormone (LH) deficiency in 38% to 91%, adrenocorticotropic hormone (ACTH) deficiency in 21% to 68%, thyroid-stimulating hormone (TSH) deficiency in 20% to 42%, and diabetes insipidus in 6% to 38%.[1]

Management

Surgery Combined With or Without Adjuvant Radiotherapy.

Surgery followed or not by radiotherapy is the most widely used first therapeutic approach for craniopharyngiomas. These tumors pose a surgical challenge because of their irregular borders and to their tendency to adhere to vital neurovascular structures, rendering safe complete removal difficult. In cases of large cystic components, fluid aspiration can lead to relief of the obstructive manifestations, but subsequent removal of the solid portion should not be delayed because of the significant risk of cyst refilling.[10,14] The extent of tumor excision has been a subject of debate and is influenced by many factors, including tumor location and presence of brain invasion.[1,15,16] In recent years, partial or limited resection combined with radiotherapy has been adopted in many centers rather than complete tumor removal, aiming to reduce hypothalamic damage and subsequent morbidity.[17] The rate of postoperative mortality in published series ranges between 0% and 5.4%.[18] A metaanalysis of 2955 patients showed an early mortality rate of 2.6% after transsphenoidal and 3.1% after transcranial surgery.[19] Various radiotherapy techniques have been applied for the irradiation of craniopharyngiomas, and doses between 50 and 60 Gy have been used for fractionated irradiation.[20,21] Radiotherapy of cystic craniopharyngiomas carries the risk of enlargement, and this needs to be taken into account during the period of irradiation.[10,20,21]

Recurrent tumors are detected at mean intervals ranging between 1 and 4.3 years following various primary treatment modalities.[1] Series with imaging confirmation of the radicality of resection report 10-year recurrence rates after gross total removal ranging between 0% and 62%, and after partial or subtotal resection between 25% and 100%. In cases of partial removal, adjuvant radiotherapy (conventional fractionated external beam) improves the local control rates (recurrence rates 10%–63% at 10 years).[1] In a systematic review, subtotal or partial resection with adjuvant radiotherapy, and gross total removal, showed similar rates of long-term tumor control.[22] Tumor control rates with newer higher precision techniques, such as fractionated stereotactic conformal radiotherapy, have remained optimal, with 5-year progression-free survival exceeding 90%.[23] Series using proton beam therapy have also provided optimal results,[21,24] but studies with long-term follow-up are necessary.

The growth rate of craniopharyngiomas varies considerably, and reliable clinical, radiological, and pathological criteria predicting their behavior are not available. Attempts to identify prognostic factors for recurrence, other than the type of treatment like age group at diagnosis, sex, imaging features, and pathological subtypes, have not provided consistent results.[1] Surgery for the management of recurrent craniopharyngiomas remains technically challenging, and the beneficial effect of radiotherapy (proceeded or not by surgery) has been clearly shown.[10,25] Recurrent lesions with significant cystic component not amenable to total extirpation may be treated by repetitive aspirations through an indwelling Ommaya reservoir apparatus.

Intracystic Irradiation. This involves stereotactically guided instillation of beta-emitting isotopes (mainly ^{32}phosphate, ^{90}yttrium, ^{186} rhenium, ^{198}gold) into cystic craniopharyngiomas. In studies with mean or median follow-up between 3.1 and 11.9 years after administration of ^{90}yttrium or ^{32}phosphorus at doses of 200 to 270 Gy, complete or partial cyst resolution was reported in 71% to 88%, stable appearances in 3% to 19%, and increase in size in 5% to 10% of cases.[26-31] New cyst formation or increase in the solid component of the tumor was found in between 6.5% and and 20%. Deterioration of vision has been reported in 10% to 58% of cases (attributed to failure of cyst collapse, formation of new cysts, increase in the solid tumor, or possibly radiation damage).[26-31]

Intracystic Administration of Sclerosing Substances. Intracystic installation of the antineoplasmatic agent bleomycin through an Ommaya reservoir connected to a catheter has been used in cystic craniopharyngiomas, with tumor control rates ranging between 0% and 100%. Direct leakage of bleomycin to surrounding tissues during the installation procedure, diffusion of the drug through the cyst wall, or high drug dose have been associated with various toxic (hypothalamic damage, blindness, hearing loss, ischemic attacks, peritumoral oedema), or even fatal, effects.[32,33] The value of this approach in the management algorithm of craniopharyngiomas, as well as optimal protocols for the administration of bleomycin, remain to be established.

Intracystic interferon-alpha has also been applied in cystic lesions, and reports suggest that it can delay disease progression. This effect, combined with the fact that it only has a few significant side effects, makes interferon-alpha a potential option for delaying definitive treatment with surgery or radiotherapy in children with cystic craniopharyngioma.[34]

Stereotactic Radiosurgery. This technique delivers a single fraction of high-dose irradiation to precisely mapped targets. Tumor volume and close attachment to the optic apparatus are limiting factors for its application. Reported 5-year progression-free survival rates range between 61% and 68% for small-volume lesions.[35-37] Stereotactic radiosurgery can be considered for well-defined residual tumors or for the control of small, solid recurrent tumors, particularly after failure of conventional radiotherapy.

Systemic Chemotherapy/Interferon-Alpha. The potential benefit of systemic chemotherapy in craniopharyngiomas has been investigated in a very limited number of patients, with rather inconclusive results.[38,39] Pegylated interferon-a-2b has also been tried,[36] but further studies are needed to clarify the impact of this approach.[40,41]

Targeted Therapy. The identification of the *BRAF* (V600E) mutation in papillary craniopharyngiomas has opened perspectives for the use of agents targeting and inhibiting mutant BRAF in cases resistant to other treatments. Case reports using BRAF and MAPK inhibitors have shown reduction in tumor volume in some patients,[8,42] and results of large trials assessing the efficacy of this treatment modality, particularly for aggressive tumors, are required.

KEY POINTS

- Subtotal or partial resection with adjuvant radiotherapy, and gross total removal, are reported to achieve similar rates of long-term tumor control, but the first option has been adopted by many centers aiming to reduce hypothalamic damage and subsequent morbidity.
- Other management modalities have been applied with variable success rates and adverse effects including intracystic administration of sclerosing substances, stereotactic radiosurgery, and systemic chemotherapy/interferon-alpha. The value of agents targeting and inhibiting mutant *BRAF* in papillary craniopharyngiomas is currently under investigation.

LONG-TERM MORBIDITY AND MORTALITY

Patients with craniopharyngiomas may suffer from significant long-term morbidities (mainly endocrine, visual, hypothalamic, neurobehavioral), attributed to damage of critical structures by the primary or recurrent tumor and/or to the adverse effects of the treatments offered.

At last assessment, pituitary hormone deficits range between 88% and 100% for GH, 80% and 95% for FSH/LH, 55% and 88% for ACTH, 39% and 95% for TSH, and 25% and 86% for vasopressin/antidiuretic hormone.[1] GH replacement in adult patients with craniopharyngioma improves free-fat mass, total and low-density lipoprotein, and quality of life, but it does not significantly decrease total body fat.[43] Based on observational studies, GH replacement is not associated with an increased risk of tumor recurrence.[44,45] A rare, challenging complication is adipsic diabetes insipidus, which confers significant risk of serious electrolyte imbalance and is one of the most difficult morbidities to manage; careful fluid balance with close monitoring of intake/output and regular checking of the weight are vital to avoid recurrent episodes of hyper- or hyponatremia that could further contribute to morbidity and mortality.[1]

Compromised vision has been reported in up to 62.5% of patients treated by surgery combined or not with radiotherapy over observation periods of 10 years.[1] Visual outcome is adversely affected by presence of visual symptoms at presentation and by daily irradiation doses greater than 2 Gy.[1]

Hypothalamic damage can manifest as hyperphagia and uncontrollable obesity, disorders of thirst and water/electrolyte balance, behavioral and cognitive impairment, loss of temperature control, and disordered sleep patterns. Obesity is the most frequent hypothalamic morbidity (reported in 26%–61% of the patients treated by surgery combined or not with radiotherapy) and results from alterations in the mechanisms involved in satiety, hunger, and energy balance.[1,10,46-48] It can be exaggerated by neurological defects, visual failure, somnolence, sleep disturbance, hypopituitarism, and psychosocial disorders.[51] The orexigenic gastric hormone ghrelin has not been found to be elevated.[52] Factors proposed to be associated with significant hypothalamic morbidity are hypothalamic disturbance at diagnosis, hypothalamic invasion, attempts to remove adherent tumor from the region of hypothalamus, and multiple operations for recurrence.[1,53,54] The management of hypothalamic obesity is very challenging and includes provision of dietary and behavioral modifications, encouragement of regular physical activity, psychological counseling, antiobesity drugs, and bariatric surgery. A systematic review and metaanalysis including 21 cases of bariatric surgery for hypothalamic obesity in patients with craniopharyngioma (six with adjustable gastric banding, eight with sleeve gastrectomy, six with Roux-en-Y gastric bypass, and one with biliopancreatic diversion) suggested that the gastric bypass group had the maximal mean weight loss achieved 12 months postsurgery.[55] Medical therapies including dextroamphetamine, the combination of diazoxide and metformin (aiming to reduce the hyperinsulinemia), octreotide (aiming to reduce hyperinsulinemia and simultaneously enhance insulin's action), glucagon-like peptide-1 analogs, and methionine aminopeptidase 2 inhibitors have been also tried, with variable outcomes.[49]

Survival of patients with craniopharyngioma can be compromised.[1,48] and the risk of cardio-/cerebrovascular and respiratory mortality is increased.[1,56,57] Hypothalamic obesity and related metabolic complications[58] may play a role in the cardiovascular morbidity and, indeed, hypothalamic involvement has been shown to have a negative impact on mortality.[59]

RATHKE'S CLEFT CYSTS

Epidemiology

Rathke's cleft cysts (RCCs) are benign, sellar, and/or suprasellar lesions originating from the remnants of Rathke's pouch.[60] They are the most common incidentally-discovered sellar lesions after pituitary adenomas. In routine autopsies, they are found in 13% to 33% of normal pituitary glands.[61,62] They have been described in all age groups, with a peak frequency between the fourth and sixth decades. Symptomatic cases of RCC are rare and account for 5% to 15% of all surgically resected sellar lesions.[63]

Pathology

RCCs are benign cystic lesions ranging from a few mm to 5 cm with usually a thick, mucoid material consisting of cholesterol and protein.[1,63,64] The cyst wall is lined by simple cuboidal or columnar epithelium with or without cilia and occasionally goblet cells secreting mucous. Pseudostratified columnar ciliated respiratory-type epithelium, squamous metaplasia (making them occasionally indistinguishable from craniopharyngiomas), and nodules of mucinous material may also be seen.[65-67] An inflammatory reaction penetrating the cyst epithelium or subjacent stroma has been described in up to 50% of symptomatic RCCs and can result in destruction of the adjacent pituitary gland and the development of hypopituitarism, and thus pituitary hormone deficits.[63-68] Coexistence of RCCs with pituitary adenomas has been reported, but this is probably coincidental.[69]

Pathogenesis

RCCs originate from embryonic remnants of Rathke's pouch, which appears on the twenty-fourth day of embryonic life as a dorsal diverticulum from the ectodermal stomodeum (primitive oral cavity). Rathke's pouch extends cranially to form the craniopharyngeal duct, and at the same time the infundibulum develops from the diencephalon as a downgrowth of the neuroepithelium. Between the third and fifth months, the anterior wall of Rathke's pouch forms the pars anterior of the pituitary, and the posterior wall forms the pars intermedia. Meanwhile, the median eminence, the pituitary stalk, and the posterior pituitary lobe develop from the infundibulum. Obliteration of the craniopharyngeal duct is associated with involution of the pouch, and, if this does not happen, a cyst develops between the pars distalis and the pars nervosa.[63,64]

Imaging Features

RCCs usually appear as well-circumscribed, spherical, ovoid, or dumbbell sellar lesions in the region of the pars intermedia.

On CT, they are usually hypo- or isodense homogeneous lesions or slightly hyperdense relative to the brain parenchyma. The enhancement is ring-like or capsular.[63]

On MRI, they are usually well-demarcated cystic lesions with homogeneous intensity signal and may show thin cyst wall enhancement. The signal intensity varies widely (hypo-, iso-, or hyperintense) and depends on the cyst content[66,70,71] (Fig. 11.2) Cysts demonstrating hypointensity on T1-weighted images and hyperintensity on T2-weighted ones have cerebrospinal fluid (CSF)-like fluid; those with hyperintensity on T1-weighted images and isointensity on T2-weighted ones have mucoid material, whereas hyperintensity on both T1- and T2-weighted images suggests the presence of blood. Cysts with a high protein concentration show high T1 signal intensity. Although hyperintensity on T2 images has been described, homogeneous T2 hypointense signal intensity is highly suggestive of RCC, facilitating the differential diagnosis from chordomas, chondroid tumors, abscesses, mucoceles, and lipomas, all showing a hyperintense T2 signal.[70] Small intracystic nodules attributed to proteinaceous concentrations demonstrate low signal intensity on T2-weighted and high signal intensity on T1-weighted images compared with that of the surrounding cyst fluid; these do not enhance, and are pathognomonic for RCCs.[70,72]

Other cystic lesions included in the differential diagnosis apart from craniopharyngiomas and cystic adenomas are dermoid cysts, epidermoid cysts, arachnoid cysts, and abscesses.

Clinical Manifestations and Pituitary Function at Presentation

Small cysts are asymptomatic, and their detection is usually incidental. When RCCs are symptomatic, the manifestations mostly relate to pressure effects to adjacent structures. Headache is the most prevalent symptom and has been associated with either hyper- or isointense content on T1-weighted MRI, mucous cyst content, or intense chronic cyst wall inflammation. Major visual field defects have been demonstrated in up to 75% of cases and correlate with cyst size, whereas cranial nerve palsies have been rarely described.[63,5-67,73]

Anterior pituitary hormone deficits at presentation vary widely, between 19% and 81%, with hypogonadism and hyperprolactinemia as the most frequent hormonal manifestations. Diabetes insipidus can be present in 0% to 19% of the cases, and inappropriate antidiuretic hormone secretion with hyponatremia has also been rarely reported.[63,65-67,73]

Apoplexy on the background of a RCC is an uncommon form of presentation.[63] Aseptic meningitis has been rarely reported and is

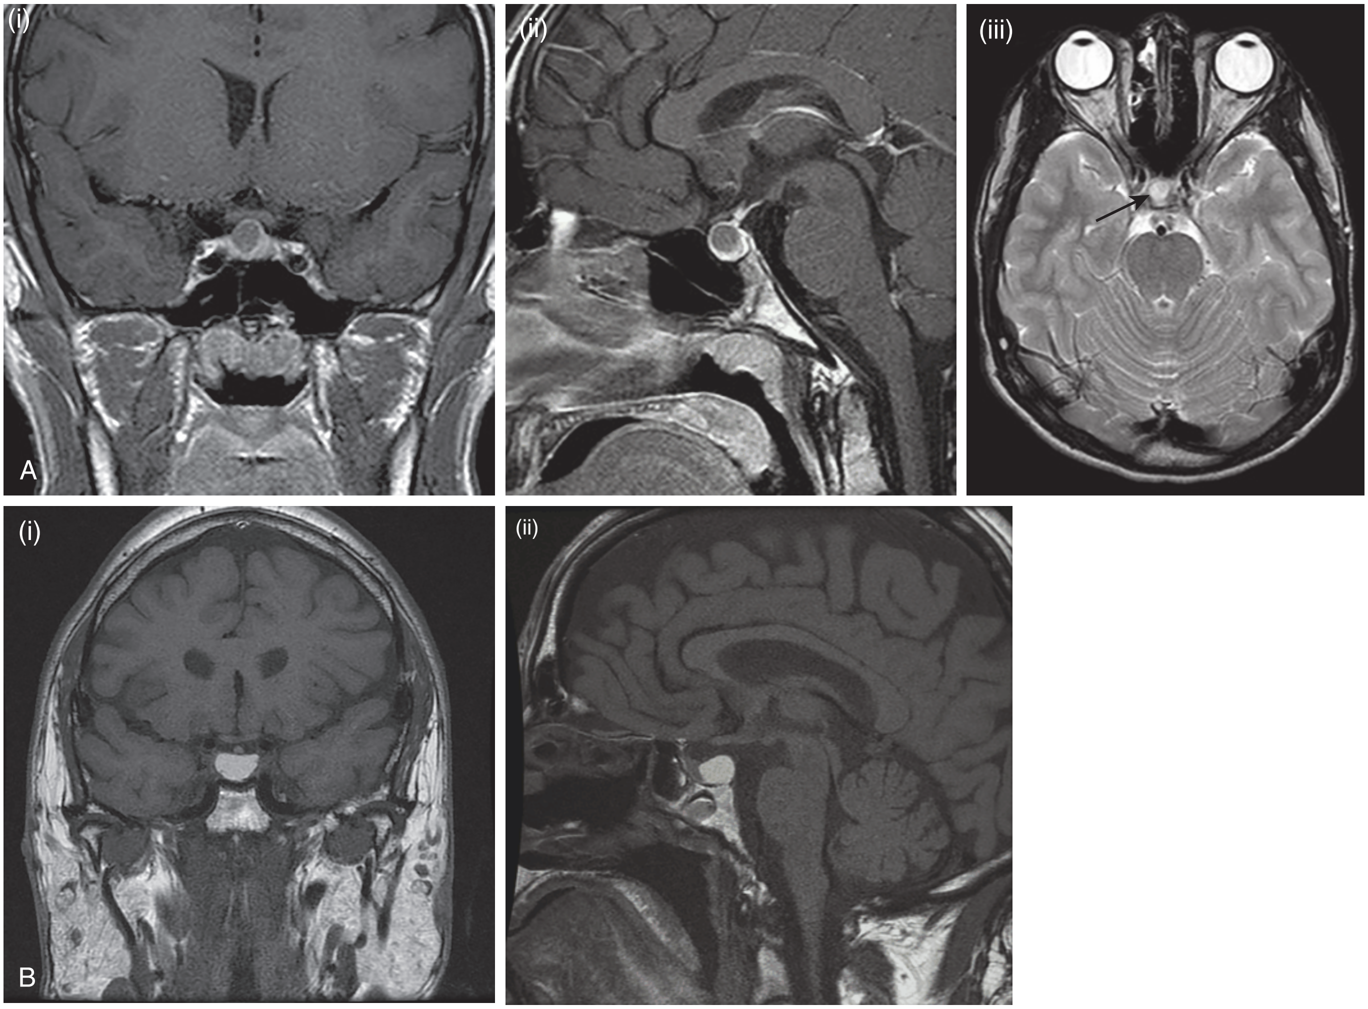

Fig. 11.2 Magnetic resonance imaging of Rathke's cleft cysts. **A**, coronal (i) and sagittal (ii) T1-weighted postgadolinium images demonstrating low signal intensity and rim enhancement. On T2-weighted images this cyst had hyperintense signal *(arrow)* (iii). **B**, Coronal (i) and sagittal (ii) T1-weighted images showing hyperintense signal. (From Trifanescu R, Ansorge O, Wass JA, et al. Rathke's cleft cysts. *Clin Endocrinol (Oxf)*. 2012;76:151–160.)

attributed to rupture of the cystic content into the subarachnoid space or to extension of the inflammation into surrounding structures.[63]

KEY POINTS

- Rathke's cleft cysts are benign lesions often discovered incidentally. Their imaging features depend on the cyst content and when symptomatic, they can present with headaches, visual deterioration and pituitary dysfunction.

Management

Small, asymptomatic RCCs do not require surgical intervention. In symptomatic ones, surgery is indicated, aiming to drain the cyst content and safely remove as much of the capsule as possible. Cyst fenestration and drainage via an endonasal/sublabial transsphenoidal approach are most commonly adopted.[63,74] Radiotherapy is not routinely required but may be considered for recurring lesions.[75]

After surgery, headaches and major visual field defects improve or resolve in a significant number of patients. Partial hypopituitarism may recover postsurgery, whereas panhypopituitarism seldom resolves.[63] Postoperative new diabetes insipidus is reported in between 25% and 67% of the cases.[63] It has been proposed that aggressive surgery with resection of the cyst wall is more commonly associated with new endocrine morbidity.[74]

Data on the endocrine and visual outcome after long-term follow-up are rather limited; in a series of 33 cases of RCCs with mean follow-up of 48 months, 50% of the patients had gonadotrophin deficiency, 42% ACTH deficiency, and 47% TSH deficiency, 39% required desmopressin treatment, and 19% had at least quadrantanopia at last review.[73]

Literature on the natural history of nonoperated presumed RCCs suggests that 26% to 94% of them remained stable (based on imaging studies or on the clinical picture) during observation periods of up to 9 years.[64,67,74,76] In a series of 29 patients with symptomatic cystic sellar lesions and imaging features consistent with RCC, spontaneous involution was reported in 31% of cases.[77] Possible mechanisms include rate of absorption of cystic fluid greater than rate of secretion or repeated cyst ruptures and leakage.[70] Enlargement of the cysts has been reported in 5.3% of incidentally found presumed RCCs during a mean follow-up period of 39 months.[76] The change in the cyst size is probably attributed to imbalance between secretion and absorption of the cyst content, intracystic hemorrhage, or infection.

Reported RCC recurrence rates after surgery range between 0% and 33% during variable follow-up periods and show wide variation

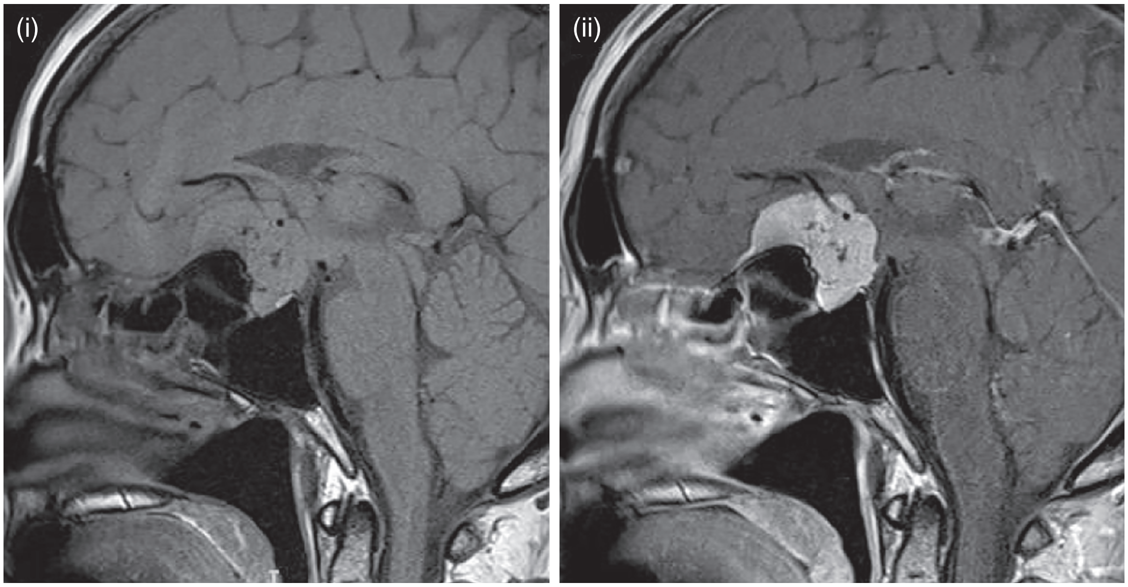

Fig. 11.3 Magnetic resonance imaging (sagittal, T1-weighted) (i) pre- and (ii) postgadolinium demonstrating a meningioma arising from the sella and extending to the suprasellar cistern. There is enhancement after gadolinium, and the characteristic dura tail is also present anteriorly.

(between 0% and 33%).[63,78] This variation may to some extent be explained by the different definitions of relapse (asymptomatic or symptomatic, requiring surgical intervention or not). In a series with mean follow-up of 48 months, the 4-year probability of recurrence was 52% at 4 years.[73] Although rare, multiple relapses have also been described.[63] The presence of squamous metaplasia in the cyst wall has been associated with increased risk of recurrence.[64,66,74] Data on extent of resection/aggressiveness of surgery and risk of relapse are not consistent.[63] The optimal management of recurrent RCCs is unclear. In asymptomatic recurrences, monitoring could be adopted, whereas in symptomatic ones, aspiration and, where possible, removal of the cyst wall have been used.[73,75] Radiotherapy after surgical intervention for a recurrent mass has also been described.[75]

KEY POINTS

- Asymptomatic Rathke's cleft cysts require no active treatment and they usually remain stable or show spontaneous involution. In symptomatic cases, surgery aiming to drain the cyst content and safely remove as much of the capsule is indicated. Recurrence after surgery is not uncommon and long-term endocrine morbidity can be significant, necessitating long-term follow-up.

MENINGIOMAS

Parasellar meningiomas account for 15% of all meningiomas and arise from arachnoidal cells of the anterior clinoid, tuberculum sellae, diaphragma sellae, or inner wing of the sphenoid.[79] Most are WHO grade I with a meningoepithelial subtype, whereas atypical meningiomas are rare.[80,81] They are more common in females. *TRAF7*, *AKT1*, and *KLF4* mutations have been reported to be common in meningiomas of the parasellar region.[82]

On CT, they appear as homogeneous masses, hyper- or isodense compared with gray matter, often with calcification present. On T1-weighted MRI, they are isointense or occasionally hypointense, with homogenous enhancement after gadolinium (Fig. 11.3). On T2-weighted MRI they can be isointense or hyperintense. Adjacent dural contrast enhancement, the dural "tail" is frequently observed and is a pathognomonic feature for meningiomas.[83] Differential diagnosis includes schwannomas, chondrosarcomas, chordomas, metastases, myelomas, and lymphomas, and a biopsy may be needed to confirm the diagnosis.

Depending on their location, they can present with visual deterioration related to optic nerve compression, oculomotor nerve palsy, trigeminal neuralgia, hypoesthesia or dysesthesia, facial palsy, cochlear and vestibular dysfunctions, epilepsy, neurocognitive dysfunction, aphasia, hydrocephalus, or symptoms of brain stem compression.[80] Parasellar meningiomas may cause hyperprolactinemia, but pituitary dysfunction is generally uncommon.

Management includes observation (in cases of nongrowing, asymptomatic lesions), surgery, surgery combined or not with radiotherapy (in cases of residual WHO grade II or WHO grade I meningiomas with aggressive features), or radiotherapy alone (for asymptomatic or mildly symptomatic parasellar meningiomas).[84] Tumor control rates are reported as more than 90% at 5 years after postoperative irradiation (fractionated stereotactic radiotherapy or gamma knife radiosurgery or cyber knife radiosurgery or proton beam radiotherapy).[84] Medical therapies are rarely needed for parasellar meningiomas; they could be considered for aggressive tumors and include the combination of everolimus and octreotide or targeted therapies.[80] Peptide receptor radionuclide therapy could be an alternative to conventional radiotherapy in extended skull base meningiomas with a low growth rate; however, this approach requires validation.

Long-term prognosis is usually favorable, but long-term follow-up is required because of the risk of recurrence. Assessment of the pituitary function is needed postoperatively in cases of surgical removal, whereas long-term endocrine follow-up is recommended when radiotherapy has been offered. Rare aggressive cases with multiple recurrences have been described.

KEY POINTS

- Parasellar meningiomas account for 15% of all meningiomas. Management is individualized, and these tumors overall have favorable long-term prognosis.

CHORDOMAS

Chordomas are low-grade, slow-growing, but locally invasive and locally aggressive tumors arising from remnants of the notochord. Skull base chordomas account for around 35% of the chordomas,[85] and based on the WHO classification they are divided in three groups: conventional, chondroid, and dedifferentiated. Most parasellar chordomas arise from the clivus. They express the transcription factor Brachyury (T), which can be used as a marker to discriminate between these tumors and other skull base lesions.[82] *PI3K* and *LYST* mutations have also been found in a small number of cases, representing plausible driver mutations for the tumor.[83,86]

Presenting manifestations of skull base and clival chordomas include headaches and/or cranial nerve dysfunctions (most frequently cranial nerve VI). Rarely, CSF leak may be detected.[87]

On CT, they are hypodense and may show calcification. On MRI, chordomas are less intense than the clivus in T1 sequences, enhance heterogeneously after gadolinium administration, and are hyperintense on T2-weighted images.[82]

First-line treatment is radical resection, particularly given that the extent of removal is a major prognostic factor.[85] Adjuvant radiotherapy is offered in cases of residual tumor, and this has to be at relatively high doses (up to 70–75 Gy), because they are relatively radioresistant.[84,88] Local control rates at 5-year follow-up have been reported at 65% with intensity-modulated radiation therapy (5-year survival 86%)[89] and 50% with fractionated stereotactic radiation therapy (5-year survival 82%).[90] Stereotactic radiosurgery may be offered for small residual or recurrent tumors, with local control rates between 21% and 72% at 5 years.[84] Currently, surgery with adjuvant proton beam radiotherapy is becoming the treatment of choice for these tumors.[85] Long-term follow-up is needed for these tumors, and in case of local or metastatic recurrence, surgical excision and radiotherapy can be considered. Chordomas are resistant to conventional chemotherapeutic agents.

KEY POINTS

- Chordomas are low-grade, slow-growing but locally invasive and locally aggressive tumors arising from remnants of the notochord. Skull base chordomas account for around 35% of the chordomas. For their management, radical resection is recommended and, when radiotherapy is offered, this requires to be in high doses due to their radioresistance. Currently, surgery with adjuvant proton beam radiotherapy is becoming the treatment of choice.

GLIOMAS

Gliomas in the parasellar area arise in the hypothalamus or optic pathway. Pathological subtypes include pilocytic astrocytoma (the most common, characterized as WHO grade I tumors), or diffuse astrocytomas (WHO grade II tumors, which have a tendency to malignant progression to anaplastic astrocytoma or glioblastoma).[91] When they involve the optic pathways, they may be linked to neurofibromatosis type 1 and can be multiple. Mutation of genes encoding proteins involved the MAPK pathway have been described in pilocytic astrocytomas.[92]

They can present with visual deterioration or retroorbital pain, proptosis, headaches, or hypothalamopituitary dysfunction (including obesity and diabetes insipidus).

On imaging, they appear as mixed tumors with cystic component and heterogeneous enhancement. The solid components are iso- or hypointense on T1-weighted images and hyper- or isointense on T2-weighted images.

The prognosis of pilocytic astrocytomas is generally optimal, with greater than 95% 10-year survival rates following surgery. Patient age and extent of tumor resection are prognostic factors. Progression to malignancy is rare in pilocytic astrocytomas. Chemotherapy does not improve progression-free survival, whereas topoisomerase inhibitors in combination with chemotherapy and new molecular agents targeting the RAS/ERK and related signaling pathways are promising novel therapeutic approaches.[91]

KEY POINTS

- Gliomas in the parasellar area arise in the hypothalamus or optic pathway. The most common pathological subtype is pilocytic astrocytoma, which has optimal prognosis after surgical resection.

GERM CELL TUMORS

Primary intracranial germ cell tumors are mostly diagnosed during the first two decades of life, and the majority arise along the midline axis, from the pineal gland to the neurohypophyseal/infundibular stalk. The most common are germinomas developing in the suprasellar area. Nongerminomatous germ cell tumors include teratomas, yolk sac tumors, embryonal carcinoma, and choriocarcinoma.[91] The main molecular alterations in germinomas include changes in the MAPK and/or phosphatidylinositol 3-kinase pathway, global low DNA methylation and chromosomal instability.[93]

They manifest as large lesions or thickening of the pituitary stalk and cause visual deterioration, diabetes insipidus, or anterior pituitary dysfunction. Precocious puberty may also be a presenting manifestation because of the secretion of human chorionic gonadotropin (hCG) by neoplastic syncytiotrophoblasts.

On CT, they usually appear as hyperdense lesions with inhomogenous enhancement and calcification. On MRI, they show variable signal intensity on T1-weighted images, whereas on T2-weighted images they are slightly isointense or hyperintense. Cystic changes may be also seen.[93]

The diagnosis is suggested by characteristic imaging features and elevated beta-hCG and/or alpha-fetoprotein in the blood or CSF. In cases with normal beta-hCG and/or alpha-fetoprotein levels, surgical biopsy for establishing the diagnosis needs to be considered.[94]

Germinomas are very radiosensitive, and craniospinal irradiation is associated with high long-term survival rates. Neoadjuvant chemotherapy may offer comparable control at lower radiation doses. In cases of relapse or metastasis, two-course chemotherapy followed by radiotherapy to the tumor region and craniospinal irradiation have shown a 98% 5-year progression-free survival rate. Nongerminomatous germ cell tumors have a more aggressive behavior, and 5-year survival rates range between 60% to 80%, after a combination of chemotherapy and irradiation. Cyclin-dependent kinase inhibitors and molecular targeted agents targeting KIT and the AKT/mTOR pathway are management options under investigation.[94]

KEY POINTS

- Primary intracranial germ cell tumors (germinomas or nongerminomatous germ cell tumors) mostly arise along the midline axis, from the pineal gland to the neurohypophyseal/infundibular stalk. They are usually diagnosed in the first two decades of life. Germinomas are very radiosensitive, whereas nonerminomatous germ cell tumors have a more aggressive behavior.

LANGERHANS CELL HISTIOCYTOSIS

LCH is a rare condition characterized by abnormal proliferation of Langerhans cells (dendritic antigen-presenting cells). It can involve any organ, including the hypothalamopituitary system. It can present at any age, but it is more prevalent in children aged below 15 years.

LCH in the parasellar area presents with diabetes insipidus and anterior pituitary dysfunction. There are no specific appearances on imaging (loss of bright spot of posterior pituitary, infundibular enlargement, hypothalamic lesion).

Diagnosis is established by biopsy of the affected area (usually the skin). Once diagnosis is confirmed, evaluation for systematic involvement is necessary.

Various chemotherapy protocols and radiotherapy are management options, with multisystem disease having worse prognosis.[95,96]

KEY POINTS

- Langerhans'cell histiocytosis is more prevalent in children and when affects the hypothalamo-pituitary system, it presents with pituitary dysfunction. Evaluation of systematic involvement is necessary and multisystem disease has worse prognosis. Chemotherapy and radiotherapy are management options.

HAMARTOMAS

Hamartomas are congenital lesions mainly detected in the hypothalamus and are mostly found in young children. Histopathologically, they consist of small neurons intermixed with glia and large neurons.

Their presenting manifestations include central precocious puberty attributed to ectopic release of gonadotropin-releasing hormone and gelastic seizures that may also be related to neurobehavioral symptoms (including cognitive deficits, attention deficit hyperactivity disorder, mood disorder).[97]

Radiologically, they appear as small nodular lesions that are iso- or slightly hypodense on CT and isointense or slightly hypointense on T1- and T2-weighted images.[91]

Observation is recommended when minor clinical manifestations are present (e.g., brief and infrequent episodes of gelastic seizures). Antiepileptic medications are not effective in controlling gelastic seizures. Surgery provides the most optimal results in seizure control and halts neurobehavioral manifestations. In cases where the tumor is difficult to resect without causing neuroendocrine damage, gamma knife radiosurgery is an alternative.[98-99] Precocious puberty is treated successfully with gonadotropin hormone–releasing agonists.

KEY POINTS

- Hamartomas are congenital lesions mainly detected in the hypothalamus. They can present with precocious puberty and gelastic seizures. Main management options include observation, surgery or radiotherapy. Precocious puberty is treated successfully with gonadotropin hormone releasing agonists.

PITUITARY METASTASIS

Pituitary metastasis is a rare manifestation of malignancy, with reported prevalences of 0.4% in radiological, 1% in surgical, and between 0.14% and 28.1% in autopsy series. Pathophysiological mechanisms are direct hematogenous spread, spread via the hypothalamic-portal vessels, meningeal spread via the suprasellar cistern, or extension from juxtasellar or skull base metastases.

Clinical manifestations include visual field impairment or optic neuropathy, cranial nerve palsies, anterior pituitary dysfunction or diabetes insipidus. Diabetes insipidus points toward the diagnosis of pituitary metastasis in a patient with known malignancy; nonetheless, contemporary data suggest that its frequency as a presenting manifestation is reducing, possibly because of earlier detection of pituitary metastatic infiltration, increased awareness of manifestations of hypopituitarism, and better availability and wider use of relevant biochemical testing. Pituitary metastasis is most frequently detected in patients with a known history of cancer (breast and lung are the most common primary sites). It may also be the first manifestation of malignancy or can be detected incidentally.

On imaging, they present as sellar or suprasellar masses or stalk thickening. Their radiological features can be nonspecific and are often not helpful in discriminating from pituitary adenoma or other sellar lesion. On MRI, they can be hypointense on T1-weighted images and hypo- or hyperintense on T2-weighted images, and they show postcontrast enhancement. Rapid growth and invasion of parasellar structures should raise suspicion of pituitary metastatic infiltration. Increased uptake on (^{18}F)-fluorodeoxyglucose positron emission tomography/CT has been detected; this is a nonspecific finding, as it can also be seen in other pathologies or even in normal pituitary tissue.

The management of pituitary metastasis aims to provide symptomatic relief (mainly of visual disturbances), with a favorable impact on quality of life, and to prevent further enlargement of the lesion. It includes surgery and radiotherapy (alone or in combination), as well as (depending on the primary malignancy) chemotherapy, immunotherapy, or hormonal therapy. Survival after the diagnosis of pituitary metastasis depends on the type and stage of primary cancer, and appears to be improving over time, possibly because of earlier diagnosis of pituitary metastatic infiltration and to improved life expectancy of cancer patients.[100]

KEY POINTS

- Pituitary metastasis is a rare manifestation of malignancy and can present as visual field impairment or optic neuropathy, cranial nerve palsies, anterior pituitary dysfunction or diabetes insipidus. Radiological features can be non-specific but rapid growth of a lesion in a patient with known malignancy should raise suspicion of pituitary metastatic infiltration.
- The management of pituitary metastasis aims to provide symptomatic relief and to prevent further enlargement of the lesion. It includes surgery, radiotherapy and depending on the primary malignancy, chemotherapy, immunotherapy or hormonal therapy.

INTRODUCTION

Normal human physiology depends on the preservation of the tonicity of the extracellular fluid (ECF). A sophisticated process of osmoregulation, which integrates the secretion and action of arginine vasopressin (AVP) and the regulation of thirst and fluid intake, maintains plasma osmolality within tightly defined limits. In healthy individuals, plasma osmolality rarely deviates by more than 2% from baseline, so abnormal plasma sodium concentrations reflect significant disturbances of normal physiology. Abnormal osmoregulation can occur as a result of AVP deficiency, which manifests as diabetes insipidus (DI), inappropriate secretion of AVP, which is the commonest cause of hyponatremia, and a number of other, less common, syndromes.

In this chapter, we will discuss the physiological control of secretion of AVP, the renal antidiuretic actions of AVP, and the interaction with the regulation of thirst. We will then apply these physiological principles to the pathophysiological mechanisms that are the basis for DI and hyponatremia.

PHYSIOLOGY OF SODIUM AND WATER HOMEOSTASIS

Synthesis and Secretion of Vasopressin

AVP is a nonapeptide synthesized in the hypothalamus that has important antidiuretic and vasopressor actions. There is considerable structural homology between AVP and oxytocin, which is also secreted from the posterior pituitary (Fig. 12.1).[1] Vasopressin is synthesized predominantly in the cell bodies of magnocellular neurones of the paraventricular nuclei (PVN) and supraoptic (SON) nuclei of the anterior hypothalamus (Fig. 12.2). The hormone is carried within neurosecretory granules down the predominantly unmyelinated axons of the magnocellular neurons, in the supraoptic-hypophyseal tract, at a speed of 2 mm per hour. The precursor undergoes successive cleavage by basic endopeptidases.[2] These axons terminate in the posterior pituitary, which is rich in fenestrated capillaries.

The gene encoding the AVP precursor is expressed mainly in the hypothalamus, and to a lesser extent in other tissues including the adrenal glands, the gonads, the cerebellum, and pituicytes in the posterior pituitary. The AVP and oxytocin genes are closely linked on chromosome 20. Posttranslational processing forms prepro-AVP-NPII, which is the precursor from which AVP is derived. The precursor consists of a signal peptide, AVP, neurophysin II (NPII, 95 amino acids), and a glycopeptide, copeptin (39 amino acids) (Fig. 12.3).

NPII is cleaved from prepro-AVP-NPII and stored in a molecule complex with AVP, prior to cleavage into the component parts and subsequent secretion into the bloodstream by exocytosis. Vasopressinergic neurons open voltage-gated calcium channels in nerve-terminal membranes. This transient calcium ion influx results in fusion of neurosecretory granules with the nerve terminal membrane and the release of AVP and NPII in equimolar amounts into the circulation.[3] Copeptin, which has unknown biological actions, is cosecreted with AVP into the circulation, and has been shown to be a stable indirect marker of AVP release.

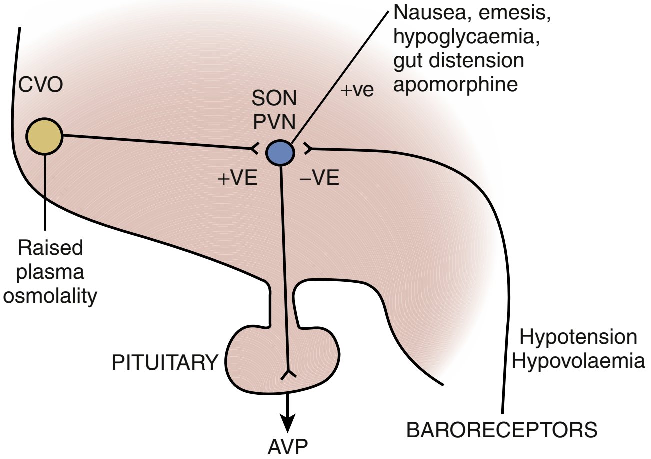

Fig. 12.2 Factors Governing Arginine Vasopressin (*AVP*) Secretion. *CVO,* Circumventricular organ (site of osmoreceptors); *PVN,* paraventricular nuclei; *SON,* supraoptic nuclei.

In addition to magnocellular neurons, which project from the SON and PVN to the posterior pituitary, there are also parvocellular vasopressinergic neurons in the PVN and the suprachiasmatic nucleus. These smaller neurons project via the median eminence to the portal vascular system of the anterior pituitary and secrete AVP and corticotrophin-releasing hormone (CRH), which in turn stimulates secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. Some parvocellular vasopressinergic neurons also project from the PVN to the forebrain, brain stem, and spinal cord. AVP is also released into the central nervous system, where it acts as a neurotransmitter and/or neuromodulator.

Cellular Action of Vasopressin

AVP binds to seven-transmembrane domain G protein-coupled receptors on the plasma membrane of target cells. Three subtypes of AVP receptor exist (V1–V3), with distinct distributions, actions, and signal transduction.

The V1 Receptor. The V1 receptor is found on the cell surface of cells in vascular smooth muscle, liver, myometrium, and platelets, as well as multiple sites in the central nervous system. AVP binding to the receptor causes activation of Gq/11-mediated phospholipase C, resulting in an increase in intracellular calcium.

Binding of AVP to V1 receptors at physiological plasma concentrations has been shown to exert a weak pressor effect.[4] AVP-mediated vasoconstriction is most noticeable in the splanchnic, renal, and hepatic artery beds. The powerful vasopressor effects of high plasma concentrations of AVP is, however, clinically significant. The pressor effect of AVP is utilized in the management of bleeding esophageal varices to promote vasoconstriction and support arterial blood pressure. Rebound hypotension on withdrawal of treatment, coupled with concerns regarding reduced cardiac output, pulmonary hypertension, hyponatremia, and bowel ischemia, have limited the use of AVP in the setting of septic shock.

The V2 Receptor. The V2 receptor is predominantly expressed on the basolateral membrane of cells in the distal convoluted tubule and collecting ducts of the kidney. Binding of AVP to renal V2 receptors stimulates the recruitment of selective water channels (aquaporins), which allow reabsorption of renal tubular water and concentration of urine. Extrarenal effects of V2 activation include factor VII release from hepatocytes and release of von Willebrand factor from vascular endothelium. AVP also causes activation of liver glycogen phosphorylase, with release of glucose into the circulation.

When AVP binds to the V2 receptors on the basolateral membrane of the cells of the collecting ducts, it triggers an increase in cytoplasmic cyclic adenosine monophosphate, which activates protein kinase (Fig. 12.4). Subsequently, there is movement of stored aquaporin-2 to the luminal membrane of the cell. Aquaporin-2 forms tetramers in the cell membrane, with each monomer acting as a water channel[5] that allows passage of tubular water into the cell. Free water reabsorption from the distal nephron, and thus urine concentration, are directly influenced by serum AVP concentrations. This relationship was established prior to the discovery of aquaporins. The AVP–V2 receptor interaction also simultaneously causes an increase in the expression of the aquaporin-2 gene, with increased generation of aquaporin-2 mRNA.

The V3 Receptor. The V3 receptor, also known as V1b, is found on corticotroph cells in the anterior pituitary. In isolation, AVP is a weak ACTH secretagogue, but when it acts synergistically with CRH it causes significant secretion of ACTH, which is physiologically important. Parvocellular neurons that coexpress AVP and CRH project via the median eminence and terminate in the hypophyseal portal bed, which provides circulation to the anterior pituitary. AVP and CRH expression by these parvocellular neurons is subject to negative feedback control by glucocorticoids. AVP has no secretagogue properties with respect to the other anterior pituitary hormones.

KEY POINTS

- Arginine vasopressin (AVP) is a peptide hormone that is synthesized in the hypothalamus and has important antidiuretic and vasopressor actions. Three subtypes of vasopressin receptor exist (V1–V3), with distinct distribution, actions, and signal transduction. The binding of AVP to renal V2 receptors stimulates the recruitment of selective water channels (aquaporins), which allow reabsorption of renal tubular water and concentration of urine.

Osmoregulation of Vasopressin Release

Water balance in healthy individuals is so carefully regulated that plasma osmolality varies by only 1% to 2% in physiological conditions, as long as there is free access to water.[6] Changes in plasma osmolality are detected by specialized osmoreceptor cells in the anterior hypothalamus (Fig. 12.2). Fenestrations in the blood-brain barrier covering the anterior hypothalamus allow the magnocellular cells of the circumventricular organs—the subfornical organ and the organum vasculosum lamina terminalis—to be bathed in plasma. Changes in plasma

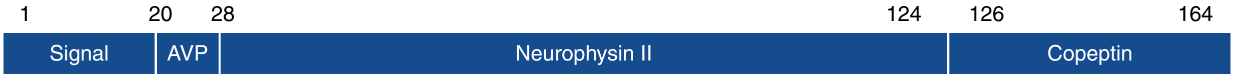

Fig. 12.3 Structure of the arginine vasopressin (*AVP*) preprohormone.

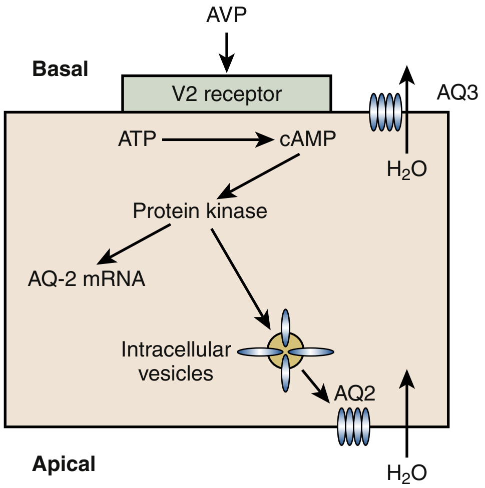

Fig. 12.4 Arginine vasopressin (*AVP*) binds to the V2 receptor and stimulates movement of aquaporin-2 (*AQ2*) to the apical membrane, where it forms a water channel for reabsorption of water (H_2O). Water moves through the apical membrane to the blood via aquaporin-3 (*AQ3*). *ATP,* Adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate.

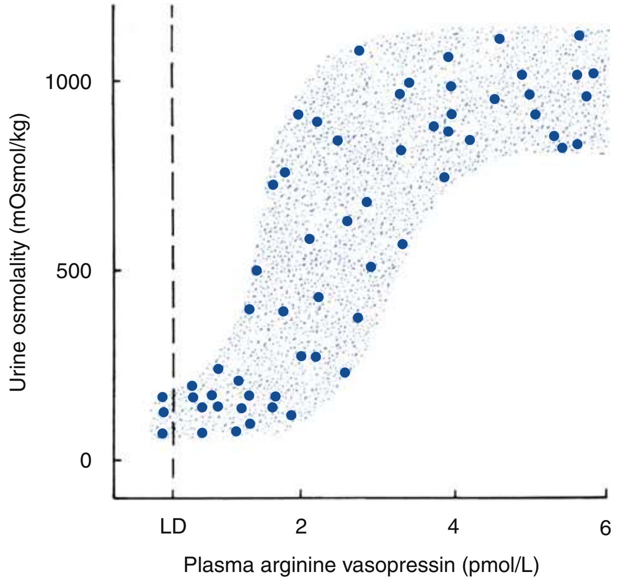

Fig. 12.5 Relationship Between Plasma Arginine Vasopressin and Urine Osmolality. Data Were Obtained During Water Loading and Fluid Restriction in A Group of Healthy Adults. Maximal Urine Concentration Is Achieved by Plasma Arginine Vasopressin Values of 3 To 4 Pmol/L. *Ld,* Limit of Detection of the Arginine Vasopressin Assay, 0.3 Pmol/L.

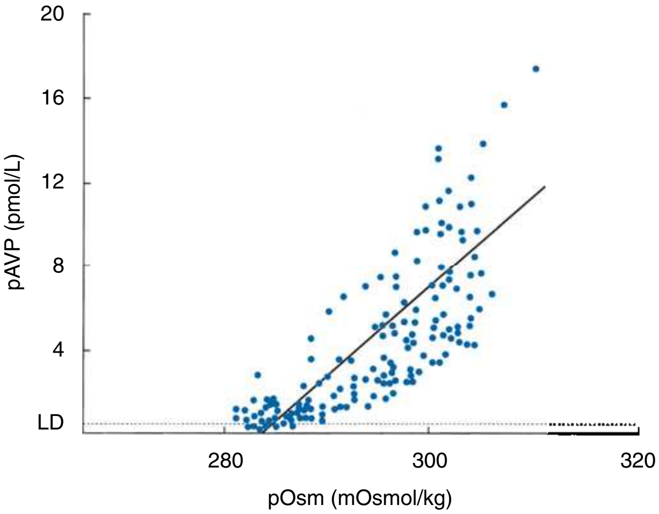

Fig. 12.6 Relationship Between Plasma Osmolality (*pOsm*) and Plasma Arginine Vasopressin (*pAVP*). Increases in pAVP in response to hypertonicity induced by infusion of 855 mmol/L saline in a group of healthy adults. The mean regression line *(dashed line)* is defined by the following equation: pAVP = 0.43 (pOsm 284); *r* = 0.96; *P* < .001. *LD,* Limit of detection of the arginine vasopressin assay, 0.3 pmol/L.

osmolality cause these hypothalamic nuclei to depolarize, sending neural signals via the nucleus medianus to the SON and PVN. An elevation in plasma osmolality causes depolarization of these nuclei, leading to increased synthesis of AVP, and secretion of AVP and copeptin from the posterior pituitary into the circulation. The osmoreceptor cells are solute-specific, in that they respond vigorously to changes in plasma sodium concentration, but less so to variations in blood urea.[7] They respond to osmotic changes induced by the intravenous infusion of mannitol, but are completely insensitive to changes in blood glucose concentrations in experimental situations.[7,8]

There is a linear relationship between plasma osmolality and plasma AVP concentrations throughout the physiological range of plasma tonicity.[9-11] If plasma concentrations are lowered by excessive ingestion of hypotonic fluid to below 280 to 285 mOsm/kg, secretion of AVP is suppressed, and plasma concentrations of the hormone are undetectable on radioimmunoassay measurement. In the absence of AVP-mediated water reabsorption from the kidney, hypotonic polyuria develops.[11] The increase in free water clearance allows plasma osmolality to rise into the normal range. If plasma osmolality rises, owing to dehydration, there is an increase in plasma concentrations of AVP, in proportion to the rise in plasma osmolality. The action of AVP, to concentrate the urine and allow reabsorption of water, restores plasma osmolality to normal. This homeostatic process occurs continuously to maintain plasma osmolality within a narrow reference range. The relationship between plasma AVP concentration and urine osmolality is shown in Fig. 12.5.

The development of sensitive radioimmunoassays has allowed the nature of this relationship to be studied experimentally. Using intravenous infusion of hypertonic sodium chloride solution to increase plasma osmolality in healthy volunteers, plasma AVP can be shown to increase in a linear fashion. Application of linear regression analysis to the data shows that a direct correlation defines the relationship between plasma osmolality and plasma AVP concentration (Fig. 12.6). The qualitative relationship is expressed by the equation pAVP = 0.43 (pOsm - 284), where pAVP indicates plasma AVP concentration and pOsm indicates plasma osmolality.[12]

This mathematical formula describes two important physiologic characteristics of the relationship between plasma osmolality and plasma AVP that are clinically relevant. The first of these is the osmotic threshold for AVP release, which is defined by the abscissal intercept of the regression line. At a mean plasma osmolality of 284 mOsm/kg, plasma AVP is secreted, with increments in secretion as plasma osmolality rises. This represents the “set point,” or the osmotic threshold for AVP release, which is identical in humans to the osmotic threshold for the onset of thirst.[12] This is an important physiological concept, as hypotonic polyuria develops when plasma osmolality is suppressed by water ingestion to concentrations below this set point. AVP detectable in the plasma by radioimmunoassay at plasma osmolalities below this is therefore, by definition, “inappropriately” elevated. Measurements of plasma AVP with ultrasensitive cytochemical methods at plasma osmolalities below the physiological threshold have led to suggestions that secretion cannot be completely suppressed by hypotonicity.[13] However, the very low concentrations demonstrated experimentally seem not to exert a significant biological effect, as they are unable to prevent hypotonic polyuria, and they could simply represent incomplete clearance of presecreted AVP.

The slope of the regression line, which represents the change in plasma AVP concentration per unit change in plasma osmolality, is the second important characteristic of the formula. This defines the sensitivity of the osmoreceptor-AVP releasing unit. Steeper slopes indicate a larger rise in plasma AVP concentrations after osmotic stimulation. Shallow slopes indicate lower rates of AVP secretion in response to hyperosmolality; a pathological example of this can be seen in partial hypothalamic DI.[14]

The osmotic threshold and sensitivity of AVP release vary significantly between individuals, but repeat testing has shown that there is good reproducibility of these parameters within individuals.[15]

Although physiological control of AVP secretion and thirst is almost entirely osmotic, the switch off of both is nonosmotic and is triggered by the act of drinking. In studies in healthy individuals who have been rendered hyperosmolar by hypertonic saline infusion,[16] drinking is associated with an immediate fall in plasma AVP and thirst, before any changes in plasma osmolality can be measured. The fall in plasma AVP is so rapid that it mimics the half-life of AVP,[16] suggesting that a neuroendocrine reflex stimulated by oropharyngeal distension switches off AVP secretion. This reflex prevents overhydration during periods of drinking in response to osmotic stimuli.

The conventional relationship between plasma osmolality and plasma AVP concentration is altered in a number of physiological and pathophysiological situations. Pregnancy causes a lowering of the threshold for AVP secretion, which is responsible for the fall in basal plasma sodium concentration during pregnancy. The sensitivity of the osmoregulatory line remains unchanged. The mechanism is unclear but may be related to increased plasma concentrations of human chorionic gonadotropin (hCG).

Normal physiological aging is associated with complex changes in osmoregulation. Basal circulating AVP concentrations increase with age, and the AVP response to osmotic stimulation has been shown to be enhanced in comparison to younger subjects. Thirst, as measured by visual analog scales, is attenuated, however, and measured water intake after osmotic stimulation intake is reduced.[17] This makes elderly humans more vulnerable to hypernatremia, and many elderly patients in long-term care institutions exhibit permanent hypernatremia, though cognitive impairment may contribute to reduced thirst in these individuals.[18]

Osmoregulation in diabetes mellitus is normal,[8] even in the presence of hyperglycemia,[19] with preserved solute specificity of both AVP release and thirst; hyperglycemia stimulates neither thirst nor AVP secretion. However, chronic hyperglycemia renders the renal tubules resistant to the antidiuretic effects of AVP, due to failure of recruitment of aquaporin-2.[20] Improved glycemic control reverses the state of partial nephrogenic DI.[20] Survivors of hyperglycemic hyperosmolar state show typical osmoregulatory changes of aging, however, with exaggerated AVP secretion and attenuated thirst in response to dehydration.[21]

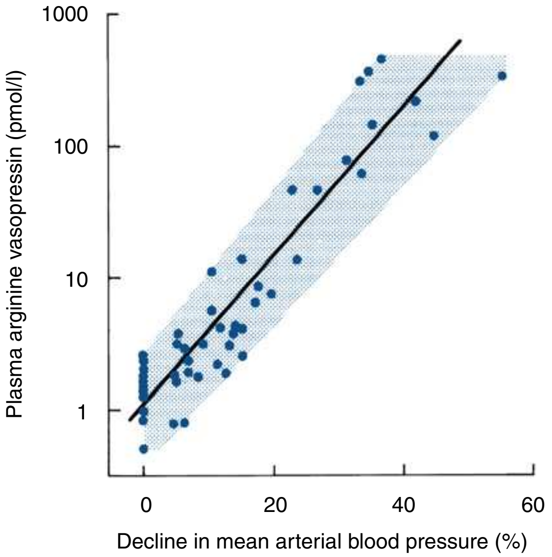

Fig. 12.7 Relationship Between Plasma Arginine Vasopressin (pAVP) and Percentage Decline in Mean Arterial Blood Pressure (MABP). Arterial Blood Pressure Was Reduced by Infusing Increasing Doses of Trimetaphan in Healthy Men. the Regression Line is Defined by the Following Equation: Log (pAVP) = 0.06 (Mabp 0.67); $r = 0.98$; $P < .001$; $n = 48$.

Baroregulation of Vasopressin Release

Physiological fluctuations in blood pressure have almost no effect on plasma AVP secretion. However, pathophysiological falls in both blood volume and pressure can stimulate very marked AVP secretion. Although minor drops in arterial blood pressure (on the order of 10%) slightly increase plasma AVP concentrations (Fig. 12.7), larger falls of 20% to 30% are highly potent stimuli to AVP secretion, causing marked elevations in plasma AVP concentrations. This makes teleological sense, as minor falls in blood pressure are common, and if AVP were to be stimulated by these small falls, humans would be in a permanent state of antidiuresis. The relationship between blood pressure and plasma AVP is shown in Fig. 12.7.

The baroreceptors are situated in the cardiac atria, the carotid sinus, and the aortic arch. They exert a tonic inhibitory effect on AVP secretion in normal circumstances, but when they are unloaded during hypotension or hypovolemia they can stimulate very high plasma concentrations of AVP via pathways quite separate from the osmoreceptors. The relationship between blood pressure and AVP is exponential rather than linear, and can be modified by neurohumoral influences such as atrial natriuretic peptides, which inhibit AVP responses, and norepinephrine (noradrenaline), which augments the baroregulatory AVP response. Baroregulatory inputs also modify osmotic AVP secretion, in that hypovolemia augments the AVP response to hypernatremia.

KEY POINTS

- Elevation in plasma osmolality is detected by osmoreceptor cells in the hypothalamus, leading to increased synthesis of arginine vasopressin (AVP) and secretion of AVP and copeptin from the posterior pituitary into the circulation. This homeostatic process occurs continuously to maintain plasma osmolality within a narrow reference range.

Other Mechanisms Regulating Vasopressin Release

In addition to osmotic and baroregulatory stimuli, AVP secretion occurs in response to nausea, manipulation of abdominal contents at surgery, and hypoglycemia. More recently, arginine infusion has been shown to stimulate the secretion of copeptin and has been suggested to be a useful test in the differential diagnosis of DI.[22]

Secretion of Copeptin

The prepro-AVP precursor is composed of AVP, NPII, and copeptin (Fig. 12.3). During axonal transport from the SON and PVN the posterior pituitary, the precursor hormone is enzymatically cleaved into the three constituent components. Copeptin, which is a larger peptide than AVP, comprising 39 amino acids,[23] is stored in secretory granules in the posterior pituitary and is secreted with AVP in response to osmotic and nonosmotic stimuli.[24] Copeptin has no known biological effects, but as it is secreted in equimolar proportions with AVP, it is a biological marker for AVP release. The half-life for copeptin is much longer than that for AVP, so it is not cleared as quickly from plasma during water loading.

KEY POINTS

- Copeptin has no known biological effects, but, as it is secreted in equimolar proportions with arginine vasopressin (AVP), it is a biological marker for AVP release.

DIABETES INSIPIDUS

Diabetes insipidus is a clinical syndrome characterized by hypotonic polyuria, due to failure to concentrate urine. There are three major causes of hypotonic polyuria, and differentiation between the three disease processes is clinically important, as the diagnosis dictates the treatment recommended to the patient.[25]

1. Central or hypothalamic DI (HDI). Polyuria is caused by insufficient AVP secretion, so there is no effective antidiuretic hormone. There needs to be a loss of at least 80% of the magnocellular neurons, which synthesize and secrete AVP, before polyuria develops.
2. Nephrogenic DI (NDI), in which AVP secretion is normal, but there is renal insensitivity to the antidiuretic effects of the hormone.
3. Primary polydipsia, where excessive fluid intake reflects abnormal perception of thirst.

A full list of the causes of DI is shown in Table 12.1.

Hypothalamic Diabetes Insipidus

HDI (also known as neurogenic, central, or cranial DI) occurs where AVP secretion is impaired such that the patient presents with a hypotonic diuresis and symptoms of polyuria and nocturia. The causative lesion for HDI spares the thirst mechanism in the vast majority of cases[26]; because thirst appreciation is intact, therefore, patients respond to the polyuria with appropriate drinking. The resultant increase in fluid intake nearly always maintains normonatremia; plasma sodium is so rarely elevated at presentation of HDI that the presence of hypernatremia, in circumstances where fluid is freely available, should always raise the suspicion of associated hypodipsia. AVP deficiency may be complete, with no detectable plasma AVP, or partial, where AVP is detectable in the plasma at low concentrations inappropriate to the ambient plasma osmolality.

HDI is rare in the general population, with an estimated prevalence of 1:25,000, but is common in the aftermath of pituitary surgery. It may occur transiently or permanently following other forms of neurosurgical intervention.

TABLE 12.1 **Causes of Diabetes Insipidus**

Hypothalamic Diabetes Insipidus	
Congenital	Hereditary (X-linked or autosomal dominant)
	DIDMOAD
Acquired	Pituitary surgery
	Tumors (craniopharyngioma, germinoma, pinealoma metastases)
	Traumatic brain injury
	Granuloma (tuberculosis, sarcoid, histiocytosis X)
	Infections (encephalitis, meningitis)
	Vascular disorders (Sheehan syndrome, aneurysms, subarachnoid hemorrhage, gastrointestinal bleed)
	Hypophysitis (A/immune, lymphocytic, immune checkpoint inhibitors)
	Idiopathic
	Pregnancy
Nephrogenic DI	
Congenital	Hereditary (X-linked recessive or autosomal dominant)
Acquired	Chronic renal disease (polycystic kidneys, obstructive uropathy)
	Metabolic disease (hypercalcemia, hypokalemia)
	Drugs (lithium, demeclocycline)
	Osmotic diuresis (glucose, mannitol)
	Amyloidosis
	Myelomatosis
Primary Polydipsia	
Compulsive water drinking	
Affective disorders, e.g., schizophrenia	
Craniopharyngiona/Rathke's cleft cyst	
Sarcoidosis	

The majority of cases of HDI are acquired during adulthood, and the commonest cause of DI in most endocrine practices is surgery for pituitary tumors. Pituitary adenomas rarely cause DI without surgical intervention, and where a pituitary mass is associated with polyuria and polydipsia, craniopharyngioma, granuloma, or hypophysitis are far more likely diagnoses. Table 12.2 shows the distribution of causes of permanent HDI in our own large series of patients. The predominance of neurosurgical causes reflects our work in conjunction with the National Neurosurgery Centre.

DI occurs following pituitary surgery in 18% to 30 % of cases,[27-30] usually within 2 days of surgery. The most common natural history is spontaneous resolution over the next 2 to 5 days. The pathophysiology of acute transient DI is thought to be surgical contusion injury to the magnocellular neurons projecting from the SON and PVN to the posterior pituitary. In some patients, however, DI persists, and AVP deficiency becomes permanent. Most neurosurgical series report a low incidence of 1% to 8% for permanent DI following transsphenoidal surgery.[27,29-31] Many published studies are retrospective, however, and have used polyuria alone as the criteria for diagnosis of DI. We found that formal screening for DI using water deprivation testing or hypertonic saline infusion identifies much higher rates of permanent DI, occurring, for instance, in 30% of patients who had transcranial surgery for pituitary adenoma and much higher figures of over 90% following craniopharyngioma surgery.[28] Many of these patients had partial DI with minor symptoms, but nearly all patients benefitted from therapeutic intervention.

TABLE 12.2 Causes of Permanent Hypothalamic Diabetes Insipidus in 231 Cases on the Beaumont Hospital Pituitary Register

Cause of Diabetes Insipidus		*n*	%

(From Behan LA, Sherlock M, Moyles P, et al. Abnormal plasma sodium concentrations in patients treated with desmopressin for cranial diabetes insipidus: results of a long-term retrospective study. *Eur J Endocrinol.* 2015;172:243–250.)

In a small minority of patients, posthypophysectomy DI follows the triple-phase response. Initially, classical postoperative DI presents in the first 2 days following surgery. However, after 4 to 8 days of hypotonic polyuria, urine output drops, and plasma sodium begins to fall, even after discontinuation of desmopressin therapy. This second, antidiuretic phase is characterized by a rise in plasma AVP concentrations, presumably from uncontrolled release of prestored peptide from damaged magnocellular neurons. If hypotonic intravenous fluids continue to be administered, the fall in plasma sodium concentration can be abrupt. The antidiuretic phase of the triple-phase response usually lasts 5 to 7 days, but there is considerable variation, from 2 to 14 days, before progression to the final phase, the development of permanent DI. It is thought permanent DI occurs when gliosis of damaged neurons prevents further AVP release.

The major factor influencing the risk of developing DI following pituitary surgery is tumor type. Craniopharyngioma is frequently associated with preoperative DI, but in addition, surgical intervention is far more commonly associated with the development of DI than surgery for any other intracranial tumor.[28,32] Surgery for ACTH-secreting pituitary adenomas has been associated with a higher risk of developing DI in a number of series.[27,29,31] The data from the literature are conflicting on the influence of tumor size on the risk of postoperative DI. One review found that a postoperative plasma sodium concentration greater than 145 mmol/L had 98% specificity in predicting the presence of DI.[32] Metastatic deposits in the hypothalamus or pituitary stalk usually have no endocrine effects, but some, particularly from carcinoma of the breast or bronchus, have been reported to produce HDI. Others tumors, such as germinoma, pinealoma, and parasellar meningiomas, can also cause HDI. Interestingly, although radiotherapy for nonpituitary cranial tumors causes anterior pituitary dysfunction commonly, it does not seem to cause DI.[33]

Lymphocytic infiltration of the neurohypophysis (infundibuloneurohypophysitis), recognized by a thickened pituitary stalk and inflammatory infiltrates of T lymphocytes and plasma cells with eosinophils, is a well-described cause of HDI, occurring in 30% of adult cases.[34]

Idiopathic DI is diagnosed less often than previously; better imaging techniques have revealed structural lesions more frequently, and there is greater awareness of autoimmune disease as a cause of DI. It has been estimated that one-third of patients previously diagnosed to have idiopathic HDI may an autoimmune etiology. The characteristics of autoimmune DI include the presence of circulating antibodies against AVP-secreting cells, young age of onset, and thickened pituitary stalk on T1-weighted magnetic resonance imaging (MRI).[35] Our own data show that patients with autoimmune DI have evidence of other organ-specific autoimmune endocrine disease, particularly thyroid disease, in one third of cases.[36]

Traumatic brain injury causes acute DI in 20% of cases,[37] some of which develop a triple-phase response similar to that seen after pituitary surgery. DI following brain injury is nearly always transient, however, with the vast majority recovering on retesting at 6 months.[38] Persistent DI in the acute phase after brain injury is a powerful predictor of acute mortality.[39] Only 7% of long-term survivors of head injury have permanent DI when formally tested with water deprivation.[40]

Sheehan syndrome is now rare in developed countries as a result of improvements in obstetric care. It is not usually associated with HDI, even when there is widespread anterior hypopituitarism, but maximal urine-concentrating ability is impaired in some patients.[41] HDI can occasionally occur in normal pregnancy, termed gestational DI, owing to increased activity of circulating vasopressinase, the placental aminopeptidase.[42] Symptoms resolve postpartum. The actions of vasopressinase can unmask partial HDI in patients with pituitary disease or can worsen symptoms in undiagnosed partial HDI. As a result, patients with pituitary disease need to be monitored during pregnancy for change in requirements for desmopressin. HDI in pregnancy must be differentiated from the transient NDI that is seen very occasionally.

Familial HDI is extremely rare. Autosomal dominant HDI is associated with loss-of-function mutations in the *AVP* gene, resulting in the production of a folding-incompetent peptide precursor that accumulates in the secretory pathway apparatus of magnocellular neurons.[43,44] This mutant precursor is responsible for an autophagocytic process, causing progressive damage and loss of vasopressinergic neurons. A single mutant allele is sufficient for this process to occur. Familial HDI almost always presents in childhood.[45]

Wolfram, or DIDMOAD, syndrome is a rare autosomal recessive, progressive neurodegenerative disorder characterized by the association of HDI with diabetes mellitus, optic atrophy, and bilateral sensorineural deafness, though other manifestations such as gonadal failure, renal outflow tract dilatation (secondary to reduced nerve fibers in the bladder wall), and progressive ataxia with brain stem atrophy may also occur.[46] The syndrome is associated with premature death, usually owing to ascending renal tract infection secondary to atonic bladder and hydronephrosis. Although DI is often reported to occur in only one third of cases, in one series where careful testing with AVP responses to hypertonic saline was performed, subnormal responses were seen in all patients.[47] Wolfram syndrome is associated with loss-of-function mutations in the *WFSI* gene on chromosome 4p16.1 that encodes an 890–amino acid glycoprotein (wolframin) found in the endoplasmic reticulum. An additional locus has been identified recently at chromosome 4q22-24, suggesting that the syndrome may be genetically heterogeneous.[47]

Nephrogenic Diabetes Insipidus

NDI occurs when renal resistance to the antidiuretic effects of AVP allows hypotonic diuresis to develop. An outline of potential causes is given in Table 12.1. Lithium therapy is the commonest cause of NDI in clinical practice: approximately 30% of patients treated with long-term lithium develop NDI. Although polyuria usually disappears with cessation of treatment, a minority of patients develop interstitial nephritis, and permanent NDI occurs. For reasons that remain unexplained, patients with lithium-induced NDI seem more vulnerable to the development of hypernatremia than patients with untreated HDI.[48] This suggests that lithium-induced NDI has coexistent impairment of thirst, with inadequate fluid intake. The mechanism for this has not been adequately defined experimentally.

Other metabolic causes of NDI include hypokalemia and hypercalcemia; NDI is usually reversible with correction of the electrolyte disturbance. Poorly-controlled diabetes mellitus causes renal resistance to AVP, which seems to be owing to failure to generate aquaporin-2 production in response to receptor binding.[8,19,20] The reversible nature of the metabolic causes of NDI illustrates how AVP-stimulated generation of aquaporins is vulnerable to metabolic and pharmacological insults.

Familial NDI is rare. X-linked-recessive familial NDI is caused by inherited loss-of-function mutations in the gene encoding the AVP V2 receptor. More than 70 different mutations have been described, affecting all aspects of receptor physiology, including expression, ligand binding, and G protein coupling.[49] The vast majority cause complete loss of function and present in infancy, though some mutations are associated with partial loss of function.[50] A minority of FNDI families have autosomal recessive NDI, with loss-of-function mutations of the gene encoding AQP2. The majority of mutations occur in the region of the gene encoding the transmembrane domain of the water-channel protein. Other kindreds have been described with an autosomal dominant NDI owing to loss-of-function mutations in AQP2 affecting the C-terminal intracellular domain of the protein. NDI is expressed in these kindreds, because the protein product of the mutant allele forms mixed oligomers with the product of the wild-type allele, resulting in sequestration within the Golgi or mistargeting to the basolateral rather than the apical membrane in a dominant negative manner.[51,52]

Primary Polydipsia

Primary polydipsia occurs when excessive fluid intake lowers the plasma osmolality to levels below the osmotic threshold for AVP secretion.[53] In the absence of circulating AVP, hypotonic polyuria develops. Many patients seem to have no underlying illness, but careful osmoregulatory studies have identified a number of abnormalities of thirst regulation. Patients typically have a low osmotic threshold for thirst that compels them to drink, even when plasma osmolality is lowered below the usual physiological thirst threshold. In addition, they have an exaggerated thirst response to osmotic challenge and an inability to suppress thirst in response to drinking, so the volume of fluid drank is in excess of that required for normal hydration.[54] Some forms of primary polydipsia are associated with psychiatric disorders, and up to 20% of patients with chronic schizophrenia have polydipsia. If these patients are simultaneously prescribed drugs that can cause syndrome of inappropriate antidiuresis (SIAD), hyponatremia is inevitable and occasionally severe. Rarely, the problem may be associated with irritative structural abnormalities in the hypothalamus or posterior pituitary, such as hypothalamic sarcoidosis or craniopharyngioma,[55] but usually brain imaging is normal.

KEY POINTS

- Polyuria can result from abnormalities in any of three fundamental components of the physiological control of water balance:
  - Subnormal arginine vasopressin (AVP) secretion, or central or hypothalamic diabetes insipidus (DI), which reflects hypothalamic or posterior pituitary damage.
  - Impaired renal concentrating ability in response to AVP (nephrogenic DI).
  - Excessive thirst appreciation (primary polydipsia).

The differentiation between these causes of polydipsia is clinically important, as the diagnosis dictates the treatment recommended to the patient.

Investigation of Diabetes Insipidus

Urine flow rates in excess of 40 mL/kg per 24 hours in adults or more than 100 mL/kg per 24 hours in infants are suggestive of DI. A careful clinical history is rarely diagnostic, but often gives valuable information in the investigation of a polyuric patient. Daytime polyuria without nocturia is a suggestive of primary polydipsia, as patients with either form of DI are unable to concentrate urine overnight, with consequent nocturia. Frequent passage of small volumes of urine may suggest prostatism, urinary tract infection, or bladder instability, rather than osmoregulatory dysfunction. A history of lithium or diuretic therapy is relevant. The presence of a mass in the pituitary fossa raises a strong diagnostic likelihood of a craniopharyngioma or germinoma; equally, the presence of DI in a patient with a sellar mass indicates that the mass is not a pituitary "adenoma." A strong family history of autoimmune thyroid disease suggests an autoimmune etiology for the DI.

Initial investigations should aim to confirm that the patient is polyuric; 15% of patients who are referred to our service for investigation of polyuria have normal urine volumes, with frequency of micturition due to urinary tract disease. A 24-hour urine volume of less than 3 L in an adult indicates that osmotic studies are unnecessary. Simple ambulatory investigations include electrolytes, calcium, midstream specimen of urine, and urinalysis; if the patient does not have glycosuria, polyuria is not due to diabetes mellitus. Clinic plasma and urine osmolality are rarely diagnostic unless the urine osmolality exceeds 700 mOsm/kg, which implies normal AVP secretion and action and therefore excludes DI. In this circumstance, the diagnosis is nearly always polydipsia, and formal osmoregulatory investigations are unnecessary. Urine osmolality is characteristically low, irrespective of the cause of polyuria. However, an elevated plasma osmolality is more likely with HDI or NDI, whereas a plasma osmolality at the low end of the reference range is suggestive of primary polydipsia.

In most patients it is necessary to proceed to a water deprivation test.[25] This is a two-step test of osmoregulatory function. The first step is an 8-hour period of dehydration. The normal physiological response is to respond to the rise in plasma osmolality with secretion of AVP, and concentration of urine to over 700 mOsm/kg. Theoretically, patients with primary polydipsia have intact osmoregulation and should therefore respond to dehydration with appropriate urine concentration. In the simplest use of this test therefore, the key measurement is the final urine osmolality, and the result answers the key question "does the patient have true DI, or not?". In patients undergoing water deprivation following hypophysectomy, this is the only step needed to make or refute the diagnosis of HDI. In clinical scenarios with a wider differential diagnosis, the second step of the test is needed.

The second step documents the renal response to desmopressin. Urine osmolality is measured at intervals after intramuscular desmopressin; in patients with HDI, there should be a normal concentrating response, with a rise in urine osmolality to greater than 700 mOsm/

kg. In contrast, patients with NDI will fail to respond to desmopressin, and urine will remain dilute. The rationale for step 2 is therefore to distinguish between HDI and NDI.

In practice, the water deprivation test does not always produce straightforward results. Surreptitious water intake can give spurious results, so the test should be undertaken with strict supervision; the most accurate results are derived from units with experience in performing the test. Partial forms of HDI and NDI are difficult sometimes to differentiate from primary polydipsia.[56] Furthermore, prolonged polyuria from any cause leads to partial resistance to the antidiuretic action of AVP.[57] This can mean that patients with severe polyuria due to primary polydipsia may appear to have partial NDI. The traditional explanation for this is that prolonged polyuria dilutes the high solute in the renal medullary interstitium, upon which water reabsorption depends. A far more likely explanation is that chronic AVP deficiency, from either HDI or long-term suppression from overdrinking, leads to failure to generate mRNA for luminal cell aquaporin-2, so that binding of desmopressin to the V2 receptor does not immediately lead to optimum water reabsorption from the urine.

The measurement of AVP, and more recently copeptin, during hypertonic (3%–5%) saline infusion has been shown to discriminate between partial cranial DI and primary polydipsia with greater diagnostic accuracy than the water deprivation test.[58] Hypertonic saline infusion leads to maximal stimulation of AVP secretion. Fig. 12.8 indicates the relationship of plasma osmolality to plasma AVP during hypertonic saline infusion in patients with varying causes of polyuria. When plasma AVP concentrations are measured with sensitive radioimmunoassays, they are a very useful diagnostic tool in this context. However, commercially available radioimmunoassays are almost uniformly unfit for purpose. Many have limits of detection that are higher than the physiological reference range for plasma AVP concentration. Access to highly sensitive and specific radioimmunoassays is limited to a few specialized centers. In addition, measurement of AVP in plasma needs an extraction step and a prolonged, two-step, double-antibody technique.[59] The assay is therefore difficult to access and difficult to perform and does not give a quick turnover of results.

The measurement of plasma copeptin offers an accessible, practical surrogate for the measurement of plasma AVP. Published data show that there is a close correlation between the two measurements.[60] Copeptin only requires small plasma volumes and uncomplicated sample handling and is easy to measure in the laboratory. It is likely to replace the measurement of plasma AVP in the approach to differential diagnosis of polyuric states, and indeed has done so in many laboratories. The plasma half-life of copeptin is longer than that of AVP, so suppression of copeptin is not as readily achieved; complex osmoregulatory disorders that require a suppression test to define the osmotic threshold for AVP may still therefore depend on the more technically difficult measurement of plasma AVP.

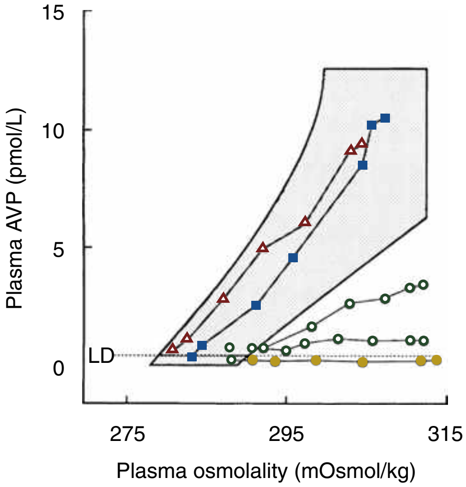

Fig. 12.8 Dynamic Tests of the Arginine Vasopressin (*AVP*) Axis in Patients with Polyuria. Plasma AVP (pAVP) and Plasma Osmolality (pOsm) Responses to Hypertonic (855 mmol/L) Saline Infusion. *Shaded Area,* Range of the Normal Response; *Red Triangles,* Normal Patients; *Blue Squares,* Patients with Nephrogenic Diabetes Insipidus; *Green and Yellow Circles,* Patients with Hypothalamic Diabetes Insipidus.

A seminal prospective multicenter study has shown that the diagnostic accuracy of hypertonic-stimulated copeptin measurement exceeds that of the traditional water deprivation test, with or without copeptin measurements. A stimulated copeptin cutoff of 4.9 pmol/L after hypertonic saline infusion had a 93% sensitivity and a 100% specificity to distinguish between primary polydipsia and HDI.[58] An elevated baseline copeptin concentration greater than 21.4pmol/L has been shown by the same group to distinguish NDI from other causes of polyuria, with sensitivity and specificity of 100%, mitigating the need for further dynamic testing in this circumstance.[61] More recent data suggest that intravenous infusion of arginine, to stimulate copeptin, can differentiate between polyuric states,[22] but there have been no studies reporting head-to-head comparisons with classical osmotic stimulation tests.

The use of a visual analog scale for thirst is helpful because patients with thirst excess show high baseline thirst readings, with exaggerated rises during the test; the most useful diagnostic parameter for primary polydipsia is the failure to suppress thirst ratings during water intake at the conclusion of the infusion.[26] On the other hand, the demonstration of absent osmoregulated thirst during osmotic stimulation is the gold standard for the diagnosis of adipsic DI (ADI).[26]

Once the diagnosis of HDI is confirmed, imaging of the hypothalamopituitary region with MRI scanning is mandatory to exclude structural lesions. Sellar tumors in patients with HDI are most often craniopharyngiomas. Identification of a stalk mass has a wider differential diagnosis that includes craniopharyngioma, germinoma, metastasis, lymphocytic hypophysitis, and stalk thickening in autoimmune HDI. A recent review of 152 patients with pituitary stalk lesions showed that 28% had DI; neoplastic (40%) and inflammatory (20%) conditions were the commonest etiologies.[62] Typical appearances may also be found in sarcoid, haemochromatosis, and other inflammatory conditions. The healthy posterior pituitary has as a characteristic bright signal on T1-weighted MRI, but this bright spot is absent in the majority of patients with HDI.[63] The intensity of the posterior lobe signal is also diminished in the elderly, in patients with anorexia nervosa, septic shock, or poorly controlled diabetes mellitus, and in hemodialysis patients. It is thought that this may represent AVP hypersecretion, and thus decreased VP-NPII complex content.

In idiopathic DI, consideration should be given to an autoimmune etiology. Measurement of thyroid function, vitamin B12, and autoantibodies is worthwhile routinely, whereas tests for primary adrenal failure should be considered where clinically indicated. Serum angiotensin-converting enzyme concentration and chest films should be considered if sarcoid is suspected. If initial hypothalamopituitary imaging is normal, it is important to repeat MRI imaging within 6 months, as clinical DI may precede the radiological manifestations of some parasellar tumors, such as germinomas.[64] It has been suggested that in younger patients, in whom germinomas are most likely to be present, repeated radiology should be performed every 3 months if initial scans are normal.[65] If stalk lesions are present, elevated serum (or cerebrospinal fluid) hCG or alpha-fetoprotein measurements may indicate the diagnosis of germinoma, and early repeat MRI to assess tumor growth is important. Biopsy should be considered early, as germinomas are best treated with chemotherapy and radiotherapy rather than surgical intervention. Dynamic tests of anterior pituitary function should be considered where structural pituitary lesions exist, though we have found that adult patients with idiopathic/autoimmune DI do not seem to have coexistent anterior pituitary hormone deficits.[36] In contrast, data in children suggest that growth hormone deficiency commonly accompanies autoimmune HDI.[66,67]

Patients with NDI should have renal investigations as appropriate, including urine microscopy, renal tract ultrasound to exclude obstruction, and tests of other aspects of tubular function. Genetic studies in suspected familial disease remain research tools.

KEY POINTS

- The first steps in the diagnostic workup of diabetes insipidus (DI) are to confirm the presence of hypotonic polyuria and to exclude other causes of polyuria, such as diabetes mellitus and hypercalcemia. In most cases of suspected DI, dynamic testing of the vasopressin-renal axis is required, of which both indirect (water deprivation test) and direct (hypertonic saline infusion with copeptin measurement) methods are possible, with the latter test showing superior diagnostic accuracy in differentiating between partial hypothalamic DI and primary polydipsia.

Adipsic Diabetes Insipidus

ADI is a rare disorder characterized by AVP deficiency that is complicated by failure to generate thirst sensation in response to hypernatremia. It is most commonly seen after clipping of anterior communicating artery aneurysms following subarachnoid hemorrhage.[68,69] The vascular supply to the osmoreceptors is derived from small arteries arising from the anterior communicating artery. It is assumed that these vessels are damaged during aneurysm clipping, with infarction of the circumventricular organs where the osmoreceptors are sited. The osmoregulatory defect is almost always permanent, although there are occasional reports of recovery.[70] Extensive hypothalamic surgery for craniopharyngioma,[69,71] and rarely pituitary macroadenoma,[71] have also been reported to cause ADI.[69]

In ADI secondary to clipping of the anterior communicating artery, there is a pure osmoreceptor defect. Osmotic stimulation with hypertonic saline causes no rise in plasma AVP or in thirst ratings, despite marked hyperosmolality. In contrast, nonosmotic baroregulated AVP secretion is completely normal, with the secretion of very high plasma AVP concentrations, often 100-fold higher than those needed for maximal urine concentration.[72] The AVP synthesis/secretion unit of the SON/PVN/posterior pituitary is thus intact, but not innervated by the osmoreceptors. In patients who have destructive surgery to the pituitary, all secretory function is lost.[72]

The diagnosis of ADI presents significant management challenges.[73] In the absence of thirst, patients are unable to perceive changes in plasma tonicity and are thus vulnerable to marked swings in plasma sodium concentration. Severe hypernatremia is a particular hazard, particularly during intercurrent illness. Management requires regular administration of desmopressin, fixed fluid intake, which may vary with climatic conditions, and regular review for measurement of plasma sodium. Hypothalamic abnormalities are often seen with ADI (Table 12.3), including hypothalamic obesity, seizure disorders, sleep apnea, and thermoregulatory disorders.[69] Episodes of dehydration are often complicated by an elevated hematocrit, with development of thrombosis, including pulmonary thromboembolism[69,74] and rhabdomyolysis.[75] Many patients die prematurely due to postsurgical complications, electrolyte abnormalities, or sleep apnea.[69,76]

Treatment of Diabetes Insipidus

Even in the absence of pharmacotherapy, the intact thirst mechanism in DI is sufficient to prevent dehydration, but the need to continually seek fluids and facilities for polyuria is a great inconvenience. The treatment of choice is desmopressin, a synthetic, long-acting AVP analog that possesses minimal pressor activity and has twice the antidiuretic potency of AVP. It can be administered as an intranasal spray, but more often is given orally in two to three daily doses. The main complication is dilutional hyponatremia,[77] which can produce

headaches, bloating, and occasionally seizures, and is more common with use of higher dosages and more frequent administration, such as three times daily. Dilutional hyponatremia can be prevented by a number of regimen adaptations:

1. Omit desmopressin once weekly. This allows an aquaresis that prevents water intoxication. This is highly effective in avoiding hyponatremia, but the day of dose omission can be severely disrupted by polyuria. This option is therefore unpopular with patients.
2. Delay the dose of desmopressin once or twice a week. This is also effective in preventing hyponatremia, but as desmopressin is administered as soon as polyuria develops, it is less disruptive of social life. However, as aquaresis is less marked, this usually has to be done twice weekly.
3. Perhaps the most effective, but most intrusive, strategy is to delay each dose of desmopressin until polyuria develops. This method allows little capacity for water retention, but many patients find it socially unacceptable.

Partial HDI (urine volume <4 L per 24 hours) can be managed with adequate fluids to quench thirst, with a nocturnal dose of desmopressin to prevent loss of sleep because of nocturia. Plasma electrolytes should be measured at regular intervals after the introduction of treatment to look for hyponatremia; a decrease in plasma sodium concentration should prompt a therapy review and introduction of one of the strategies documented above. In contrast to hyponatremia, outpatient hypernatremia almost never occurs in DI, where thirst is intact. However, hypernatremia is common during acute illness, particularly where vomiting or diarrhea increase nonrenal water losses.[77]

NDI due to an acquired metabolic problem is best managed by addressing the underlying electrolyte abnormality and maintaining adequate hydration while function recovers. For patients with congenital NDI or those with an acquired defect that is irreversible, a number of additional measures, including thiazide diuretics (hydrochlorothiazide, 25 mg/24 hours); prostaglandin inhibitors such as nonsteroidal antiinflammatory drugs (ibuprofen, 200 mg/24 hours), and dietary salt restriction can be used. All probably work through a combination of reducing glomerular filtration rate and interference with the diluting capacity of the distal nephron, and all are partially effective at best. Data in rats suggest that there may be therapeutic potential in the use of sildenafil for NDI, but there are no data in humans.[78] Fluid replacement remains the cornerstone of treatment of NDI.

As with other causes of DI, the approach to primary polydipsia is to address the underlying cause. This may be difficult, as the urge to drink in primary polydipsia may be powerful and distressing. Hyponatremia is unusual unless there is coprescription of a medicine that stimulates AVP secretion. Switching treatment to alternative agents that do not stimulate AVP may help those patients with chronic schizophrenia and a history of hyponatremia. Individuals with persistent primary polydipsia are at risk of hyponatremia if treated with desmopressin, so accurate diagnosis is important. Reduction in fluid intake is the only rational treatment.

KEY POINTS

- Long-term treatment with desmopressin can control the thirst and polyuria of hypothalamic diabetes insipidus (HDI). Hyponatremia is a relatively common complication of desmopressin treatment in patients with HDI and intact thirst; such patients should be counseled to allow regular periods of free water clearance to prevent this. On the other hand, patients with adipsic diabetes insipidus are at significant risk of hypernatremia, and management of this condition can be particularly challenging.

HYPONATREMIA

Morbidity and Mortality

Hyponatremia is the most common of the electrolyte disturbances seen in clinical practice, occurring in approximately 15% of hospitalized patients.[79] There is considerable evidence that shows that hyponatremia is associated with increased morbidity, mortality, and length of hospital stay.[80,81] Mild hyponatremia has been considered to be asymptomatic, but cognitive decline and gait instability[82] leading to increased falls,[83] bone fractures,[84] and osteoporosis[85] have all been reported. Hyponatremia has consistently been associated with increased mortality in almost every published study,[80,86,87] although some authors have suggested that hyponatremia is only a marker of severity of the underlying disease,[88] rather than the *de facto* cause of excess death. However, treatment of hyponatremia has been associated with a reduction in mortality in a number of studies.[89,90]

Differential Diagnosis of Hyponatremia

The causation of hyponatremia is myriad, and importantly, the presentation, behavior, and mortality vary according to etiology. The most widely used clinical approach is to classify the etiology of hyponatremia according to ECF status into hypo-, eu-, and hypervolemic hyponatremia (Table 12.4). This requires careful use of clinical and biochemical data, and the distinction between euvolemia and mild hypovolemia is particularly challenging. However, accurate categorization of patients according to ECF volume status and urine electrolyte excretion does allow the initiation of etiology-specific treatment. In addition, as there is good evidence that mortality in patients with hypervolemic and hypovolemic hyponatremia is substantially higher than in euvolemic hyponatremia,[91] careful categorization by blood volume allows more accurate prognostic predictions.

Hypovolemic Hyponatremia. Hypovolemic hyponatremia is characterized by ECF depletion due to loss of fluid through the skin, gastrointestinal tract, or kidney. Diminished blood volume causes off-loading of baroreceptors, with powerful stimulation of AVP release. Hyponatremia may develop, particularly in conjunction with

TABLE 12.4 Differential Diagnosis of Hyponatremia

	Clinical features	Urine sodium <20 mmol/L	Urine sodium >40 mmol/L
Hypovolemic	Dry mucus membranes, decreased skin turgor, tachycardia, hypotension (in particular orthostatic), low CVP, raised urea	Dehydration	CSW Diuretics Addison disease Salt-losing nephropathy
Euvolemic	Normal pulse and blood pressure	SIAD with FR	SIAD ACTH insufficiency Hypothyroidism
Hypervolemic	Peripheral edema, ascites, pulmonary edema	Inappropriate IV fluids Cardiac failure Cirrhosis	Renal failure

CSW, Cerebral salt wasting; *CVP*, central venous pressure; *FR*, fluid restriction; *IV*, intravenous; *SIAD,* syndrome of inappropriate antidiuresis; *ACTH*, adrenocorticotropic hormone.

inappropriate administration of hypotonic fluids. Demonstration of low central venous pressure is the gold standard diagnosis, but this is an invasive procedure that is impractical to perform in most cases. A clinical diagnosis of hypovolemia is based on orthostatic hypotension, tachycardia, dry mucous membranes, and decreased skin turgor, together with laboratory clues such as raised urea-to-creatinine ratio and elevated uric acid concentration. Urinary sodium concentration is nearly always low, often less than 10 mmol/L, in hypovolemia, due to activation of the renin-aldosterone system, and mineralocorticoid-induced sodium retention at the kidney. Hypovolemia with elevated urine sodium concentrations indicates that the site of volume/sodium loss is the kidneys, or that the patient is taking diuretics, particularly thiazides.

Primary adrenocortical failure is an important cause of hypovolemic hyponatremia. Combined glucocorticoid and mineralocorticoid deficiency leads to renal salt and water loss; hypotension causes baroreceptor-stimulated AVP release, which causes water retention, further lowering plasma sodium concentration. The biochemical picture differs from that of central adrenal insufficiency, where mineralocorticoid secretion is retained; severe hypovolemia and hyperkalemia are not seen.[92]

Hypervolemic Hyponatremia. Hypervolemic hyponatremia is characterized by peripheral or sacral edema, ascites, and elevated central and jugular venous pressures, all clinical parameters of fluid overload. Arterial underfilling leads to a baroreceptor mediated increase in AVP secretion and antidiuresis, activation of the renin-angiotensin system and secondary hyperaldosteronism, and increased sympathetic tone. Secondary hyperaldosteronism leads to sodium retention but the relative water excess, resulting from increased plasma AVP concentrations and upregulation of aquaporin-2 water channels, causes the development of hyponatremia.

Euvolemic Hyponatremia. Patients without clinical evidence of volume expansion or depletion should be considered euvolemic. Spot urinary sodium concentration is greater than 20 to 30 mmol/L in most euvolemic patients, though dietary sodium restriction can lead to misleadingly low urinary sodium levels. Other supporting laboratory parameters in euvolemia include low blood urea and low serum uric acid. The majority of cases of euvolemic hyponatremia are due to SIAD, and it is this variant of hyponatremia that is most often referred to endocrine services.

THE SYNDROME OF INAPPROPRIATE ANTIDIURESIS

Introduction

SIAD is the commonest cause of hyponatremia in clinical practice. The syndrome was first described in 1956 by Frederic Bartter and William Schwartz, in two patients with lung carcinoma who had severe hyponatremia at presentation.[93] In an elegant series of experiments in which fluid restriction was alternated with fluid loading, the investigators demonstrated that the patients were in a state of antidiuresis. They hypothesized that their patients manifested a clinical syndrome of inappropriate antidiuresis secondary to excess circulating antidiuretic hormone, well before the hormone itself was characterized. Subsequent development of sensitive radioimmunoassays allowed the measurement of plasma AVP, and their classic clinical description and pioneering pathophysiological hypothesis were substantiated by published reports of elevated plasma AVP concentrations in patients with the syndrome.[94] SIAD is now recognized to occur in wide spectrum of disease states; however, differentiation of SIAD from other causes of hyponatremia remains important to the prescription of appropriate treatment regimens.

Causes of Syndrome of Inappropriate Antidiuresis

SIAD is associated with a great number of illnesses and most often presents as a coincidental biochemical manifestation of the causative disease. The most common causes of SIAD are summarized in Table 12.5. The etiology of SIAD is divided into four main clinical categories: malignancy, pulmonary, pharmacological, and neurological causes. Bartter and Schwartz first described SIAD in association with bronchogenic lung carcinoma. In small cell carcinoma of the lung, SIAD is relatively common and has been associated with poor outcome. Most neoplasms have now been reported to cause SIAD, and the association between malignant disease and SIAD is so strong that a patient presenting with SIAD, general malaise, and unexplained weight loss should be considered to have an underlying malignancy until proven otherwise.

SIAD is also commonly associated with intracranial diseases, particularly traumatic brain injury (TBI),[37,38,40] where almost all cases resolve spontaneously with recovery from brain injury. Over 50% of patients with subarachnoid hemorrhage (SAH) develop hyponatremia in the first week following the bleed, and 80% of these are due to SIAD.[95,96] A significant proportion of patients presenting biochemically with SIAD after both TBI[39] and SAH[96] have hyponatremia due to acute glucocorticoid deficiency; such patients respond to treatment with hydrocortisone rather than fluid restriction. SIAD also commonly occurs after hypophysectomy and after surgery for primary brain tumors (see earlier). Cerebral salt wasting (CSW) is an extremely rare cause of neurosurgical hyponatremia; a prospective analysis of 100 cases of SAH that included careful clinical and biochemical assessment of volume status failed to reveal a single case.[96] Low plasma osmolality, high urine osmolality, and high urinary sodium concentration are features of both SIAD and CSW; a key to distinguishing between the two

TABLE 12.5 Etiology of Syndrome of Inappropriate Antidiuresis (SIAD)

Malignancy	Drugs	Pulmonary	Intracranial Pathology	Miscellaneous
SCC lung	DDAVP	Pneumonia (esp. mycoplasma)	Tumors	Multiple sclerosis
Mesothelioma	PGs	TB	Meningitis	Guillain–Barré syndrome
GI tract	SSRIs	Abscess	Encephalitis	Acute intermittent porphyria

is the demonstration of an initial period of natriuresis and hypovolemia preceding the onset of hyponatremia in CSW.

Many drugs are important clinical causes of hyponatremia. The selective serotonin reuptake inhibitors (SSRIs) are thought to cause SIAD by direct stimulation of AVP secretion by serotonin.[97] SIAD usually occurs in the first few weeks after commencing SSRIs, particularly in elderly patients.[98] It has been estimated that 12% of hospitalized patients on SSRI therapy develop SIAD.[99] Psychotropic such as phenothiazines, haloperidol, and tricyclic antidepressants all cause SIAD. Many patients who have conditions treated with psychotropic drugs also have abnormal thirst, and if these patients develop drug-induced SIAD, they can develop very significant hyponatremia. For instance, up to 20% of patients with chronic schizophrenia have psychogenic polydipsia, and excess fluid intake can precipitate severe hyponatremia. MDMA ("ecstasy") is thought to stimulate both AVP release and thirst as a result of hyperthermia, and this has been implicated in the development of cases of life-threatening hyponatremia.[100]

SIAD needs to be distinguished from exercise-associated hyponatremia (EAH),[101] where the electrolyte profile mimics SIAD. The pathophysiology is different, however. EAH occurs in athletes who ingest excessive hypotonic fluid during exercise, with resultant dilutional hyponatremia. Women, marathon runners racing for more than 4 hours, and athletes of low body mass index are most at risk.[102] Although some athletes with EAH fail to suppress AVP, EAH should probably be considered to be distinct from SIAD.

Pathophysiology of Syndrome of Inappropriate Antidiuresis

SIAD occurs by definition when AVP secretion is not suppressed when plasma sodium concentration falls below the osmotic threshold for AVP release. Zerbe and colleagues identified four different types of SIAD, depending on the pattern of AVP secretion[94] (Fig. 12.9):

1. Type A is the most common form of SIAD (40%). Characteristically, type A patients exhibit excessive, random secretion of AVP, with loss of the close linear relationship between plasma osmolality and plasma AVP. Plasma AVP concentrations fluctuate widely in this variant, with no relationship to ambient plasma osmolality, but with consistent antidiuresis and inappropriate urine concentration despite hyponatremia. Type A is common in lung cancer; *in vitro* studies have demonstrated that some lung tumors synthesize AVP,[103] and tumor tissue stains positive for AVP mRNA.[104] However, type A SIAD also occurs also in nonneoplastic disease where ectopic AVP secretion could not be implicated. Plasma AVP concentrations in type A SIAD are not suppressed by drinking,[105] which makes patients vulnerable to the development of severe hyponatremia.
2. Type B is also common (40%). The osmotic threshold for AVP release is lowered—a "reset osmostat"—such that secretion of AVP occurs at lower plasma osmolalities than normal. At plasma osmolalities above this reset threshold, the linear relationship between plasma AVP and plasma osmolality is preserved. Equally, because AVP is suppressed at plasma osmolalities below the lower reset threshold, overhydration leads to suppression of AVP release. A hypotonic diuresis then develops, which protects against the progression to severe hyponatremia. Similar lowering of the osmotic threshold occurs in hypovolemia and hypotension, leading to speculation that the function of afferent baroregulatory pathways is disturbed in these patients.
3. Type C is a rare condition characterized by failure to suppress AVP secretion at plasma osmolalities below the osmotic threshold. Plasma AVP concentrations are thus inappropriately high at low plasma osmolalities, but there is a normal relationship between plasma osmolality and plasma AVP at physiological plasma osmolalities. This variant may be due to dysfunction of inhibitory neurons in the hypothalamus, leading to persistent low-grade basal AVP secretion.
4. Type D is a rare clinical picture of SIAD without detectable circulating AVP.[106] A nephrogenic syndrome of inappropriate antidiuresis (NSIAD) was postulated after two male infants were described in whom gain-of-function mutations in the V2 receptor led to a clinical picture of SIAD with undetectable AVP levels.[107] Various gain-of-function mutations have now been described.[108]

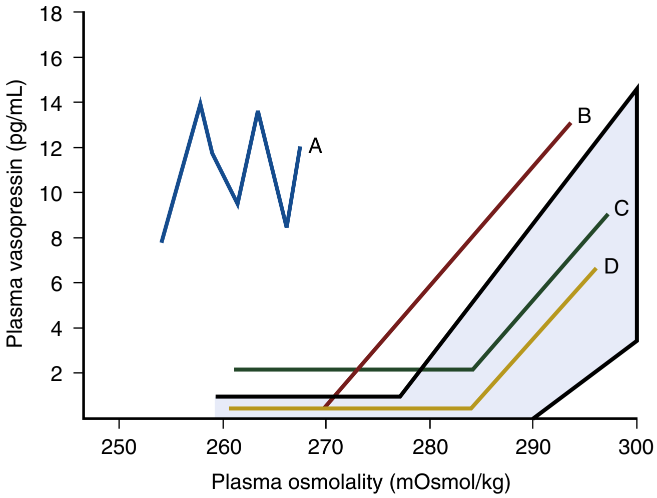

Fig. 12.9 Summary of the four different patterns of arginine vasopressin secretion in syndrome of inappropriate antidiuretic hormone secretion.

Studies in rat models of SIAD have demonstrated that the increase in water reabsorption is secondary to AVP-mediated expression of renal aquaporin-2,[109] with a consequent increase in aquaporin-2 protein excretion in the urine.[110] Aquaporin-2 recruitment has been shown to be reversible by administration of a V2 receptor antagonist,[109,111] which provides the scientific rationale for the use of AVP antagonists in the treatment of this condition. Prolonged SIAD is associated with "escape" from antidiuresis, with downregulation of AQP2 mRNA and protein expression.

Although patients with SIAD have ambient plasma osmolalities that are below the physiological osmotic threshold for thirst, they continue to drink apparently normal fluid volumes. In experiments where patients with SIAD of mixed etiology were infused intravenously with hypertonic sodium chloride solution, the osmotic threshold for thirst was lowered to a setting that was identical for that of AVP.[105] The parallel lowering of the thresholds for thirst and AVP release in SIAD ensured the maintenance of fluid intake, predisposing to persistent hyponatremia.

As fluid intake is maintained in the face of reduced free water clearance, patients with SIAD can develop severe hyponatremia. However, hyponatremia is often limited by "escape from antidiuresis." This protective homeostatic mechanism occurs when the kidney begins to increase free water clearance despite inappropriate plasma AVP concentrations.[112] Initial natriuresis is followed by an increase in urine flow,[113] with consequent water loss; this allows plasma sodium to stabilize and, occasionally, to rise. Although plasma sodium concentration does not usually rise into the normal physiological range during escape from antidiuresis, the development of severe hyponatremia is prevented.

Diagnosis of Syndrome of Inappropriate Antidiuresis

The essential criteria for diagnosis of SIAD are presented in Table 12.6. There are two additional supplemental criteria—raised plasma AVP concentration and abnormal water load test—but in clinical practice they are rarely used. Water-loading a patient with SIAD runs the risk of inducing symptomatic hyponatremia, and this procedure should therefore be restricted to centers with considerable experience in managing disorders of water balance. Plasma AVP and copeptin concentrations are elevated in almost all causes of hyponatremia and are therefore rarely of diagnostic benefit in hyponatremic patients.

The minimum data set for the diagnosis of SIAD is hyponatremia in a euvolemic patient with inappropriate concentrated urine (osmolality >100 mOsm/kg), elevated urine sodium (>30 mmol/L), and exclusion of cortisol and thyroid hormone insufficiency. Urine osmolalities in excess of 100 mOsm/kg indicate inappropriate urine concentration and are compatible with the diagnosis of SIAD. In clinical practice, the ascertainment of the minimum data set for the diagnosis is poor,[114] which raises concern that hyponatremic patients may be misclassified as having SIAD, and therefore be treated inappropriately, on the basis of inadequate investigation.

Differential Diagnosis of Syndrome of Inappropriate Antidiuresis

Glucocorticoid Deficiency. The major differential in euvolemic hyponatremia is ACTH deficiency, which causes hyponatremia with a biochemical profile identical to classical SIAD. Management with glucocorticoid replacement restores normonatremia,[115] whereas fluid restriction, which is first-line therapy for SIAD, is deleterious, in that it worsens hypovolemia.[116] Measurement of plasma cortisol is essential, as clinical signs do not reliably differentiate between glucocorticoid deficiency and SIAD.[117] Cortisol deficiency impairs free water clearance, and glucocorticoids suppress AVP release, such that elevation of plasma AVP concentrations has been reported in ACTH-deficient patients who develop hyponatremia.[118]

The differentiation of SIAD from glucocorticoid deficiency is particularly important in hyponatremic patients with neurosurgical conditions.[119] SIAD is the commonest cause of neurosurgical hyponatremia,[120] but acute pituitary dysfunction occurs commonly following TBI and subarachnoid hemorrhage. ACTH deficiency was reported in 16% of patients with acute[37] and 12.7% patients with chronic head injury[121]; recent data suggest that up to 80% of patients have inappropriately low plasma cortisol concentrations in the acute phase of brain injury, some of whom present as having SIAD.[39] Up to 10% of cases of SIAD presenting after SAH may be secondary to acute ACTH/cortisol deficiency.[96] In neurosurgical patients who present with biochemical manifestations of SIAD, coexistent hypoglycemia or hypotension suggest the diagnosis of hypopituitarism. In patients presenting with SIAD against a background of TBI, SAH, or intracranial hemorrhage, we consider that the possibility of acute hypopituitarism should be considered in the differential diagnosis. Published data have shown that, in euvolemic hyponatremia, a random plasma cortisol greater than 300 nmol/L (10.9 µg/dL) predicts a pass response to intramuscular *synacthen* (*cosyntropin*), so this seems to be a reasonable screening test. Where a random sample falls below this, the diagnosis should be confirmed with a *synacthen* test.

TABLE 12.6 Essential Criteria for the Diagnosis of Syndrome of Inappropriate Antidiuresis (SIAD)

Decreased plasma osmolality of the ECF (Posm <280 mOsm/kg H_2O)
Inappropriate urinary concentration during hyposmolality (Uosm > 100 mOsm/kg H_2O, normal renal function)
Clinical euvolemia
Elevated urinary sodium excretion (>30 mmol/L) on normal salt and water intake
Absence of other potential causes of euvolemic hypoosmolality, particularly hypothyroidism, hypocortisolism, and diuretic use

ECF, Extracellular fluid; *Posm*, plasma osmolality; *Uosm*, urine osmolality.

Hypothyroidism. Hyponatremia in hypothyroidism is rare, though life-threatening hyponatremia is occasionally seen in severely myxoedematous patients.[122,123] Hypothyroid patients have elevated AVP responses to subtle volume contraction, with increased recruitment of AQP2.[124] However, the hyponatremia is probably multifactorial. Hypothyroidism so rarely produces SIAD[125] that the need to check thyroid function tests has been questioned.

KEY POINTS

- The minimum data set for the diagnosis of syndrome of inappropriate antidiuresis (SIAD) is hyponatremia in a euvolemic patient with inappropriate concentrated urine (osmolality >100 mOsm/kg), elevated urine sodium (>30 mmol/L), and exclusion of cortisol and thyroid hormone insufficiency. The major differential diagnosis in euvolemic hyponatremia is adrenocorticotropic hormone deficiency, which causes hyponatremia with a biochemical profile identical to classical SIAD and should not be missed.

TREATMENT OF HYPONATREMIA

The key issues that determine optimum management of hyponatremia are accurate assessment of the underlying cause and awareness of the chronicity of low plasma sodium concentrations. While acute hyponatremia is a medical emergency that can lead to death if untreated, chronic hyponatremia has long been thought of as a benign condition, and is often left underinvestigated and untreated. However, emerging evidence of the role of hyponatremia in falls, osteoporosis, fractures, length of stay, and mortality now provides a rationale for its treatment also. Recent data have suggested that effective treatment of hyponatremia can improve cognitive function[126] and gait[82] and reduce mortality.[89]

Factors Affecting Therapy

Clinical guidelines have stressed that the urgency of treatment of hyponatremia is dependent upon the presence of symptomatic cerebral irritation. As patients with chronic hyponatremia adapt to the electrolyte derangement, it is patients with sudden-onset hyponatremia who are most likely to exhibit signs of cerebral irritation. Neurological signs of hyponatremia almost always reflect cerebral edema, leading to increased intracranial pressure, so the clinical imperative to treat hyponatremia is more urgent when the rate of fall of plasma sodium concentration has been rapid.

Acute hyponatremia is defined as a fall in plasma sodium concentration of less than 48 hours' duration and is generally regarded as a medical emergency,[127] with high mortality in the absence of intervention.[128] In contrast, patients with chronic hyponatremia (>48 hours' duration) are much less likely to develop symptoms, as they undergo cerebral adaptation by extruding solutes such as potassium and organic osmolytes into the plasma. This prevents osmotic movement of water into the brain, and as a result cerebral edema is avoided. In contrast, in acute hyponatremia this time-dependent process does not occur, with the subsequent development of brain edema and cerebral irritation.[129]

Treatment of Chronic Hyponatremia Owing to Syndrome of Inappropriate Antidiuresis

Clear guidelines for the management of hyponatremia due to SIAD have been published in both the United States[127] and Europe.[130] Although modest hyponatremia of greater than 130 mmol/L has traditionally been regarded as not in need of treatment, there is increasing evidence that comorbidities such as gait instability and falls,[131] fractures,[84] and osteoporosis[85] may occur even with modest hyponatremia. After careful exclusion of treatable underlying conditions such as glucocorticoid deficiency, there are a number of options for the treatment of SIAD.

Fluid Restriction. Clinical guidelines consistently recommend fluid restriction as first-line treatment, despite the absence of a strong evidence base. Fluid restriction of 1 L per day is occasionally sufficient to correct hyponatremia,[132] although the rate of rise of plasma sodium is not predictable. A recent randomized controlled trial of fluid restriction versus no treatment for chronic SIAD showed that fluid restriction produces a modest elevation of 3 mmol/L in plasma sodium, which is sustained over a month of therapy.[133] However, few patients normalized plasma sodium concentration over the study period. Fluid restriction, which is inclusive of all fluids, including intravenous fluids and liquid dietary supplements, is difficult to maintain in patients with cognitive difficulties, in patients with a history of polydipsia, or in patients receiving intravenous medications. In addition, in more severe hyponatremia, the degree of fluid restriction necessary to correct hypoosmolality may be too difficult to maintain. The US guidelines have stressed that, if urine osmolality is greater than 500 mOsm/kg, the Furst equation ratio is greater than 1, or 24-hour urine volume is less than 1.5 L, fluid restriction is unlikely to be effective.[127] In clinical practice 60% of patients have one of these predictors, and 40% have two,[134] and in a prospective study both urine osmolality and urine sodium were associated with nonresponse to fluid restriction.[135] In theory, therefore, it should be possible to select patients, based on these criteria, who will respond best to fluid restriction.

Pharmacological therapy tends to be reserved for cases that are unresponsive to fluid restriction, but it is clear from the disappointing results of prospective studies[133] that a substantial number of patients fall into this category.

Demeclocycline. Demeclocycline is a tetracycline antibiotic that induces NDI by a postreceptor effect. Demeclocycline can be effective but is not licensed for use in all countries. There is a variable response to this agent, and a systematic review of the literature in 2015 found a lack of clinical or economic evidence to support its use.[136] In addition, side effects, including photosensitivity and nephrotoxicity, particularly in patients with liver disease, can complicate chronic therapy. Occasionally, hypernatremic dehydration can develop if polyuria is marked. With the development of new therapies, there seems to be little justification for using this treatment.

Urea. Urea therapy has been advocated as second-line therapy in the European guidelines,[130] and in one small study was found to be as effective as vaptans.[137] The same group has reported data suggesting, from uncontrolled studies, that urea is a safe therapy for use in euvolemic hyponatremia in intensive care patients.[138] A recent retrospective review of nonrandomized patients found urea to be effective and safe,[139] but prospective randomized trials are awaited. Urea is contraindicated in renal failure, the taste is unpleasant, and it is difficult to source; its use is limited to a few countries.

Furosemide With Sodium Chloride Replacement. The combination of furosemide, which produces a natriuresis and a diuresis, with sodium chloride tablets to replace urine sodium loss, has been advocated for many years for the treatment of SIAD. A recent randomized controlled trial showed no benefit to the addition of furosemide and sodium chloride, with or without fluid restriction, compared with fluid restriction alone; there was, however, a higher incidence of acute kidney injury and hypokalemia in patients treated with furosemide and sodium chloride,[140] so better evidence is needed before recommending this treatment.

Vasopressin Receptor Antagonists. The specific V2 receptor antagonists (vaptans) offer a specific antidote to AVP-mediated hyponatremia.[141] These agents act as "aquaretics," in that they increase free water excretion without a natriuresis and offer a therapeutic effect regardless of the etiology of raised AVP. The selective V2 antagonist tolvaptan is licensed for use as an oral agent in Europe, whereas in the United States both tolvaptan and the combined V1a/V2 antagonist conivaptan[142] are available.

The efficacy and safety of oral tolvaptan in ambulatory patients was explored in two randomized, double-blind, placebo-controlled multicenter trials (SALT-1 and SALT-2) consisting of 448 patients with hyponatremia of multiple etiologies, including SIAD, heart failure, or cirrhosis.[143] The administration of tolvaptan resulted in a significant increase in serum sodium concentration compared with placebo, without the requirement of water restriction. The group treated with tolvaptan was found to have greater improvement in quality of life, as assessed by the Short Form–36 questionnaire. The incidence of overrapid correction of hyponatremia was low, and no patients developed central pontine myelinolysis. A subsequent extension study, the SALTWATER trial, showed that the safety and efficacy of tolvaptan were maintained over a mean of almost 2 years,[144] with no significant adverse effects. A subgroup analysis of the effects of tolvaptan on the SIAD cohort of the SALT studies confirmed the efficacy of the drug in SIAD.[145] The use of high-dose tolvaptan for the treatment of polycystic kidney disease has been associated with elevated serum transaminases,[146] so liver function tests should be monitored in patients on long-term treatment.

Summary of Second-Line Therapies. Although fluid restriction is the recommended first-line therapy in international guidelines, randomized prospective trials have shown modest effects, with relatively few patients attaining correction targets.[133] In addition, the "real world" effects of fluid restriction therapy have been even less impressive, as shown by the results of the Hyponatremia Registry, where the effect of fluid restriction was not significantly better than no treatment.[147] There is therefore a clear need for second-line therapy. The guidelines differ in their recommendations, in that the European Guidelines strongly endorsed urea therapy while advising against tolvaptan,[130] whereas the US guidelines endorsed physician choice over second-line therapy, while recognizing that the vaptans had the strongest supportive trial data.[127] Cost considerations mitigate against widespread use of vaptans, whereas urea is not universally available as a therapeutic compound and has a taste that is unpalatable. There is a clear need therefore for a cost-reasonable, effective alternative to fluid restriction.

Potential New Therapies. New agents are therefore being explored for the treatment of SIAD. A recent study found that empagliflozin, the sodium glucose cotransporter-2 inhibitor used as an oral hypoglycaemic agent, had significant effects on plasma sodium concentration in patients with hyponatremia due to SIAD. In a randomized comparison to fluid restriction, a short course of empagliflozin had more significant sodium-elevating effects than fluid restriction (10 vs. 7 mmol/L over 4 days) in hospitalized patients with SIAD; the effects were more marked in patients with severe hyponatremia.[148] Long-term effects were not assessed, nor was there time for the development of side effects, and the drug will certainly need further study before licensing for treatment of SIAD. However, the results were promising. The mechanism of action is almost certainly increased free water clearance secondary to glycosuria.

Apelin is a neurovasoactive peptide that is expressed in the SON and PVN, where it is thought to exert an inhibitory effect on AVP release.[149] It has been hypothesized that patients with SIAD have an imbalance in the apelin/AVP ratios, which contributes to the state of antidiuresis.[150] Apelin expression has also been demonstrated in the kidney, where apelin analogs have been shown in animal studies to reduce the generation of aquaporin-2 by AVP,[151] and the effects of apelin to reduce AVP antidiuresis may be an amalgamation of hypothalamic and renal effects.[152] Recent rat data has shown that an apelin-R agonist can increase urine osmolality and increase plasma sodium in hyponatremic animals.[153] Apelin clearly has profound effects on modulating AVP secretion and action, and its agonists have the potential for a therapeutic role in SIAD.

Treatment of Acute Hyponatremia

Untreated severe hyponatremia of acute onset, especially when associated with evidence of cerebral irritation, is potentially fatal.[154,155] However, treatment is potentially hazardous, as rapid correction of hyponatremia renders the patient vulnerable to the risk of osmotic demyelination, a devastating complication characterized by spastic quadriparesis and cranial nerve palsies. The risk of osmotic demyelination is highest when chronic hyponatremia is rapidly corrected; patients with chronic hyponatremia have often adapted, and leakage of inorganic ions equalizes the osmolality across the blood–brain barrier. This reduces brain swelling and intracranial pressure. As a result, patients with chronic hyponatremia tend to have fewer symptoms of cerebral irritation and are therefore less in need of heroic rescue. Conversely, osmotic demyelination during treatment is less of a risk when hyponatremia is of acute onset. Therefore, those patients at most risk of death from acute hyponatremia also have the least risk of developing osmotic demyelination.

Guidelines now advocate treatment paradigms based on the speed of onset of hyponatremia and the presence of symptoms of cerebral irritation, rather than how low the plasma sodium concentration is.[127,130] This is in contrast to earlier interpretations, which linked symptoms directly to the severity of hyponatremia.[156] Therefore, current recommendations are that rapid reversal of hyponatremia, using intravenous hypertonic sodium chloride solution, should be reserved for patients with hyponatremic encephalopathy and good evidence of the rapid onset of hyponatremia.

The traditional treatment of acute symptomatic hyponatremia has been the steady intravenous infusion of 3% sodium chloride solution, with the aim of correction of plasma sodium concentration by no more than 0.5 mmol/L/hour, or 12 mmol/L over 24 hours.[157] Recent expert panel recommendations have suggested some changes to this traditional guideline.[127] The first change is that the aim for the elevation in plasma sodium should not be for an evenly distributed increase across the first 24 hours. Observations in normonatremic neurosurgical patients, that acute elevation in plasma sodium concentration of 4 to 6 mmol/L reduces signs of cerebral herniation and lowered intracranial pressure by 50%,[158] prompted a review of available evidence in hyponatremic patients. This concluded that a similar rise in plasma sodium concentration of 4 to 6 mmol/L is sufficient to reverse the more dangerous effects of acute hyponatremia.[159] As the development of cerebral herniation due to acute hyponatremia occurs rapidly and is associated with significant mortality,[128] a new approach was recommended for hyponatremia with neurological symptoms. This entailed the acute elevation of the plasma sodium, initially by 3 to 5 mmol/L over 2 to 4 hours, by the intravenous injection of 50- to 100-mL boluses of 3% sodium chloride, supported by frequent checking of plasma sodium concentration; this strategy was considered more likely to reverse cerebral edema, reduce intracranial pressure, and prevent seizures.[127] The remainder of the target rise in plasma sodium can occur over 24 hours. This strategy was tested by prospective study of patients with acute symptomatic SIAD treated with bolus 3% saline, as compared with historical controls who had been treated with slow intravenous infusion.[160] A comparison of the rate of rise of plasma sodium concentration is shown (Fig. 12.10); bolus 3% saline led to a quicker rise in plasma sodium concentration in the first 6 hours, but similar rises at 24 hours. The important endpoint was a faster return to normal Glasgow Coma Scale (GCS) in the group treated with bolus injections. Although there were no cases of osmotic demyelination in either group, the need to relower plasma sodium because of overcorrection was slightly higher in the bolus group.

The second alteration in the US guidelines was the target rise in plasma sodium concentration over the first 24 hours.[127] As osmotic demyelination has occasionally been reported with rises in plasma sodium concentration within the 12 mmol/L/24 hours guidelines, the

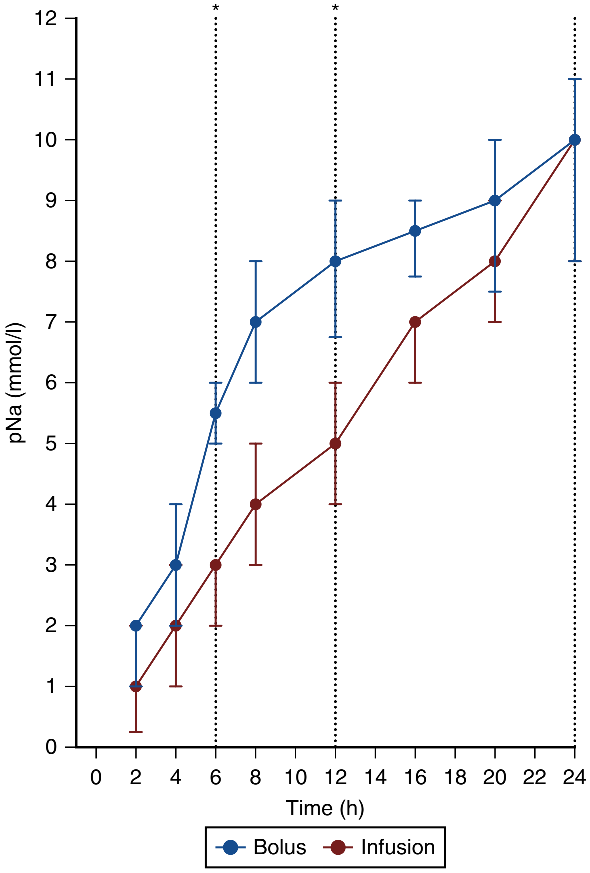

Fig. 12.10 Change in plasma sodium (*pNa*) concentration in patients with symptomatic hyponatremia due to syndrome of inappropriate antidiuresis (SIAD) treated with bolus versus slow infusion of hypertonic saline.

24-hour target was lowered to 8 mmol/L, with a maximum tolerable rise of 12 mmol/L. Lower targets still were recommended for patients with higher risk of osmotic demyelination, for instance those with malnutrition, liver disease, or alcohol abuse.[127]

There seems to be a greater awareness of the mortality associated with acute severe hyponatremia. Although early studies have shown high mortality associated with acute hyponatremia,[128,156] more recent studies have shown much lower rates,[90] which have been attributed to more specialized endocrine input and more careful attention to electrolyte monitoring.

KEY POINTS

- The key issues that determine optimum management of hyponatremia are accurate assessment of the underlying cause and awareness of the chronicity of low plasma sodium concentrations. Patients with chronic hyponatremia may have minimal symptoms, and cerebral herniation is uncommon. In this scenario, it is the risk of osmotic demyelination syndrome from overly rapid correction of plasma sodium concentration that guides treatment regimens. Fluid restriction is the recommended first-line therapy for chronic syndrome of inappropriate antidiuresis (SIAD) in international guidelines; however, randomized prospective trials have shown modest effects on plasma sodium concentration. Second-line therapies for SIAD are limited by cost, availability, adverse effects, and/or lack of prospective randomized data. Acute symptomatic hyponatremia is a medical emergency, and recent international guidelines emphasize the importance of rapid initial correction of plasma sodium correction, initially by 3 to 5 mmol/L over 2 to 4 hours, using boluses of hypertonic saline.

CONCLUSIONS

There have been significant developments in the areas of DI and hyponatremia in the past decade. The diagnostic approach to polyuria syndromes is evolving. Dynamic direct stimulation tests of AVP secretion, with measurement of the surrogate marker copeptin, look set to take the place of the traditional gold standard water deprivation test in differentiating partial HDI from primary polydipsia. In hyponatremia, prospective randomized trial data have shown fluid restriction produces only a modest improvement in plasma sodium concentration in patients with chronic SIAD. V2 receptor antagonists have been shown to be effective in randomized controlled trials, but their widespread use is limited by cost and concerns about risk of overcorrection. New affordable treatment options for SIAD are needed, both for clinical practice and to enable future studies to go one step further and demonstrate treatment effect on complications of hyponatremia. Future studies of hyponatremia treatment should focus not only on correction of hyponatremia as an endpoint, but also improvements in associated comorbidities such as unsteady gait, poor cognition, falls, and fractures. Finally, the debate as to whether treatment of hyponatremia results in improvements in mortality risk remains open, and a multinational prospective trial is underway to examine this.

ANATOMY OF THE HYPOTHALAMUS

The hypothalamus is located in the forebrain, positioned either side of the lower cerebral third ventricle. Its floor comprises the optic chiasm and tracts, pituitary stalk, mamillary bodies, and posterior perforated substance. Anteriorly, it borders the lamina terminalis and the anterior commissure, and posteriorly the midbrain. The upper superior surface of the hypothalamus is continuous with the thalamus and epithalamus, while its lateral sides border the zona incerta and internal capsule. Branches of the internal carotid enter and supply the ventral surface of the hypothalamus. Fig. 13.1 shows a sagittal view of the complex organization of the hypothalamus, its relationship to the pituitary gland, and its vasculature. The location of the hypothalamic nuclei, the hypothalamic neurohormones secreted, and their main functions are shown in Table 13.1. The median eminence is at the base of the hypothalamus and forms the interface at which the neuroendocrine parvocellular neurons make contact with a capillary plexus formed from superior hypophyseal branches of the internal carotid. The cell bodies of the parvocellular neurons are located in the paraventricular nucleus (corticotrophin-releasing hormone [CRH], thyrotropin-releasing hormone [TRH]), arcuate nucleus (dopamine, growth hormone–releasing hormone [GHRH]), medial basal hypothalamus (gonadotropin-releasing hormone [GnRH]), and periventricular zone (somatostatin). Magnocellular neurons producing and secreting oxytocin and vasopressin are located in the supraoptic nucleus and paraventricular nucleus and extend to the posterior pituitary.

Blood Supply of the Hypothalamus

The arterial supply to the hypothalamus arises from small perforating vessels that arise from different parts of the circle of Willis and pass through the anterior and posterior perforated substances. In addition, the superior hypophyseal arteries, which are branches of the internal carotid arteries, supply the optic chiasm and adjacent parts of the hypothalamus. The superior hypophysial arteries form a capillary network in the median eminence that recombine to form portal vessels that pass down the pituitary stalk, where they divide into another capillary network perfusing the anterior pituitary, which then drain into venous vessels via the cavernous sinus and, in turn, the jugular systemic circulation. The direction of blood flow in the portal vessels is thought to be predominantly hypothalamus to pituitary. The concept of neurohumoral control by the hypothalamus of the anterior pituitary by the secretion of releasing factors into portal vessels at the median eminence was championed by Geoffrey Harris, and his seminal work has been elegantly reviewed in the literature by those who worked with him in Oxford.[1,2]

The Median Eminence and Tanycytes

The median eminence is the functional interface between the hypothalamus and the pituitary, and comprises hypothalamic axons and nerve terminals, a dense network of capillaries and glial cells. It is organized into three zones: the innermost ependymal layer that lines the floor of the third ventricle, the internal zone, and the external zone. The internal zone lies beneath the ependymal layer and contains subependymal cells, astrocytes, and parvicellular and magnocellular fibers of the hypothalamo-hypophysial tract *en route* to the posterior pituitary. The external zone is the location where hypothalamic regulatory factors are released from parvocellular nerve terminals into the capillaries that will form the pituitary portal vessels. Ependymal cells in the ependymal layer form an interface between the cerebrospinal fluid (CSF) and the extracellular space of neural tissue of the median eminence, and are lined with microvilli, indicating a role in controlled transport of molecules, and complexes of desmosomes and tight junctions at their apical surface that prevent intercellular diffusion of larger molecular weight molecules. The ependymal layer also contains the soma of tanycytes, which send a short apical process to the ventricle surface and a long basal process across the three layers to the external zone of the median eminence. Here the tanycytes are in close association with parvocellular nerve terminals and fenestrated capillary beds that will form the pituitary stalk portal vessels. Tanycytes can be distinguished by the prominent cytoplasmic intermediate filaments along their length by electron microscopy (Fig. 13.2). Tanycytes also extend cytoplasmic processes to hypothalamic nuclei concerned with energy balance, such as the arcuate nucleus, and are considered important for their role in sensing energy and endocrine homeostasis through their strategic

TABLE 13.1 Hypothalamic Nuclei and their Functions

Nucleus	Location	Major hormones/function
Supraoptic (SON)	Anterolateral, above the optic nerves	AVP; osmoregulation Oxytocin: regulation of milk ejection in lactation and uterine contractions
Paraventricular (PVN)	Dorsal anterior, adjacent to the third ventricle	Magnocellular PVN: AVP and oxytocin, same functions as SON above
Arcuate	Medial basal, close to the third ventricle	GHRH: stimulation of growth hormone GnRH: regulation of gonadotrophins FSH and LH (primates) Dopamine: inhibits lactotroph PRL secretion Somatostatin: inhibition of GHRH secretion Regulation of appetite: neuropeptide Y, alpha-MSH, cocaine- and amphetamine-related transcript
Periventricular	Anteroventral	Somatostatin: inhibition of pituitary somatotroph GH secretion
Ventromedial	Ventromedial	GHRH: stimulation of GH
Dorsomedial	Dorsomedial	Somatostatin: inhibition of GHRH release; appetite satiety center of the hypothalamus
Lateral hypothalamus	Lateral	Hunger center of the hypothalamus; orexins, melanin-concentrating hormone
Preoptic area	Preoptic area	GnRH in rodents (few in primates)
Anterior hypothalamus	Anterior	Thermoregulation cooling center and regulation of thirst
Posterior hypothalamus	Posterior	Thermoregulation heating center
Suprachiasmatic	Above the optic chiasm, anteroventral	Circadian rhythm regulator, AVP and vasoactive intestinal peptide, neurons project to the PVN

AVP, Arginine vasopression; *GHRH,* growth hormone–releasing hormone; *GnRH,* gonadatropin-releasing hormone; *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *PRL,* prolactin; *MSH,* α-melanocyte–stimulating hormone; *GH,* growth hormone.

location bridging hypothalamic neurons, CSF, and the blood, signaling the physiological and metabolic status of the animal.[3] Seasonal changes in neural-tanycyte interactions in the median eminence have been reported in seasonal breeding animals.[4] The extensive tanycyte network is a key component of the median eminence neurovascular interface, such that hypothalamic neurosecretory nerve terminals are distributed within the tanycyte network. In long photoperiod conditions (nonbreeding season), a marked tanycyte barrier between GnRH terminals and the basal lamina of the median eminence has been demonstrated, constraining GnRH release.[4] In contrast, in the short

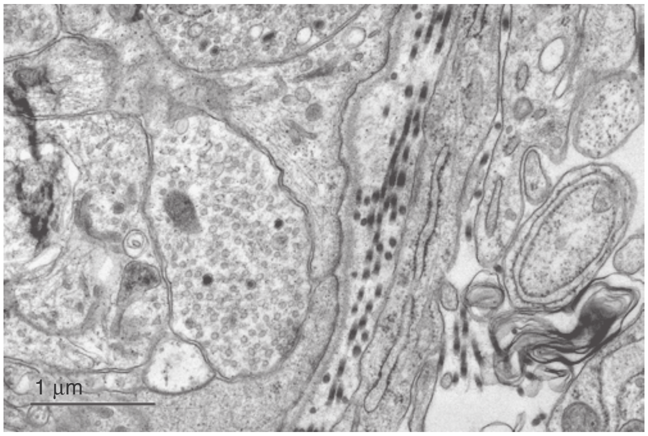

Fig. 13.2 Electron micrograph of the median eminence (ovine) illustrating a tanycyte end foot processes surrounding nerve terminals adjacent to the perivascular space containing collagen fibrils. The tanycytes can be distinguished by their intermediate filaments and the nerve terminals by secretory granules and vesicles.

photoperiod, GnRH nerve endings extend through to the basal lamina and perivascular space of the median eminence capillaries, and the tanycyte barrier is more dispersed.[5]

ANATOMY AND HISTOLOGY OF THE PITUITARY

The pituitary gland has a bilaterally symmetrical bean-shaped structure, approximately 13 mm in transverse, 8 mm in anterior-posterior diameter, and 6 mm deep. In adults it weighs on average 0.6 g (range 0.4–0.8 g), is typically smaller in men than in women, and enlarges in pregnancy.

The pituitary lies within a depression of the sphenoid bone at the base of the skull termed the pituitary fossa or sella turcica, which is lined by dura mater and covered by an extension of the dura mater called the diaphragma sellae. The pituitary is connected to the brain by the pituitary stalk (infundibulum), which penetrates through a small opening in the diaphragma sellae from the base of the hypothalamus above. Below the pituitary fossa is the sphenoid air sinus, and laterally on each side is the cavernous sinus and internal carotid artery. Superior and anterior to the pituitary and the pituitary stalk is the optic chiasm, which because of its close proximity can be compressed by growth of the pituitary, for example, adenomas resulting in "tunnel vision." The pituitary consists of two parts: the adenohypophysis (or anterior pituitary) and neurohypophysis (or posterior pituitary) (see also Chapters 4 and 15). The adenohypophysis comprises the pars distalis, pars intermedia, and pars tuberalis. The pituitary stalk comprises fenestrated portal vessels from the median eminence that supply the anterior pituitary and the large unmyelinated axons of magnocellular neurons originating in the supraoptic and paraventricular nuclei of the hypothalamus that terminate in the posterior pituitary.

The Blood Supply of the Pituitary

The anterior pituitary gland has a rich and intricate vasculature,[6] as beautifully revealed in scanning electron microscopy imaging of vascular casts of the rhesus monkey.[7] It is the most richly vascularized of all mammalian tissues, receiving approximately 0.8 mL/g/min of blood from the hypothalamo-hypophyseal portal system. Portal vessels pass down the pituitary stalk into the pars distalis and adjacent pars tuberalis and branch into a secondary plexus of fenestrated capillaries that facilitate drainage of endocrine secretions into the systemic circulation and the circulation of regulatory hormones from the hypothalamus and the periphery (thyroid, gonads, adrenal cortex). The capillaries comprise endothelial cells and basement membrane, with underlying mural cells termed pericytes. The capillaries reform themselves into efferent lateral hypophysial veins that drain into the cavernous sinus and subsequently the internal jugular venous system. The capillaries are not sinusoids, because there are no large spaces in their walls. The perivascular space between the vascular border and the secretory cells can be relatively large, and contains fibers of connective tissue such as collagen. Hormones released into the extracellular space diffuse into capillaries through fenestrations in the endothelial lining (Fig. 13.3). The posterior lobe receives its blood supply from the inferior hypophyseal branches of the internal carotid artery. Venous drainage of the posterior pituitary is to the cavernous sinus and circular sinus, and in turn the internal jugular vein. The intermediate lobe, in contrast, has little vasculature. For a more comprehensive review of the pituitary arterial supply and its clinical relevance, see Cironi et al.[6]

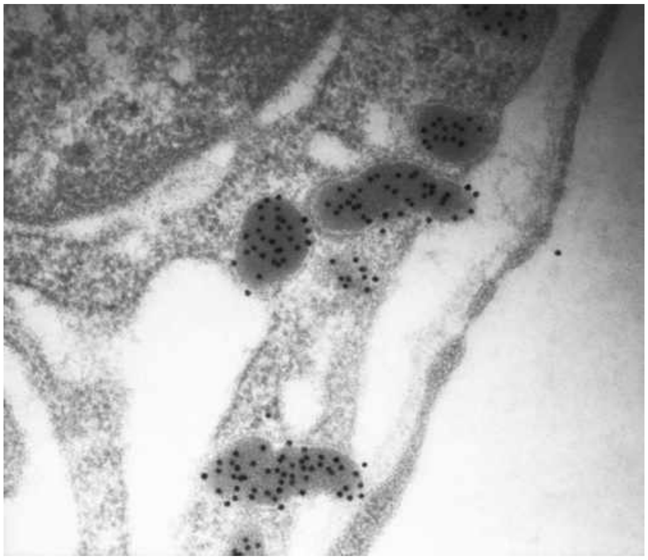

Fig. 13.3 High-power electron micrograph illustrating the perivascular space between a type 1 lactotroph and the fenestrated capillary endothelium (rat). Secretory granules are characteristically irregular in shape and immunogold-labeled for prolactin. Particles are 15 nm.

The Pars Intermedia

The pars intermedia (or intermediate lobe) of the anterior pituitary contains mostly α-melanocyte–stimulating hormone (MSH/proopiomelanocortin [POMC])-expressing cells surrounding a cleft between the anterior and posterior lobes known as the pituitary cleft or Rathke's cleft. In adult humans this is a thin layer of cells that often merge with the anterior pituitary, but is more prominent as a distinct zone of uniform cells in other mammals. The function of the mammalian intermediate lobe POMC-cells is not clear, but in lower vertebrates, amphibia, and fish, secretion of MSH, under the control of multiple hypothalamic nuclei, is involved in the control of pigmentation.[8] It is thought that the intermediate lobe is likely a developmental remnant of Rathke's pouch. The neural control and function of the intermediate lobe across vertebrates has been comprehensively reviewed by Low.[8]

The Pars Tuberalis

The pars tuberalis (PT) is composed of mainly follicular cells (similar in morphology to folliculo-stellate cells) and thyroid-stimulating hormone (TSH)-positive secretory endocrine cells (with sparse small secretory granules) that form a sheath surrounding the pituitary stalk pars nervosa neurons and hypophyseal stalk portal vessels extending

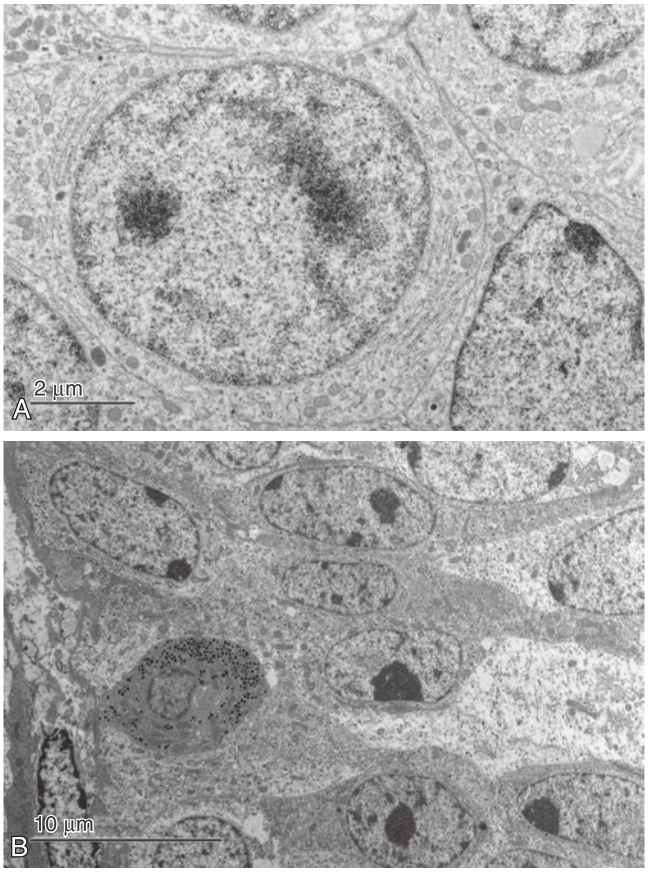

Fig. 13.4 Electron micrographs of a pars tuberalis thyrotroph within the ovine pars tuberalis (**A**)—note the very small sparse granules and extended rough endoplasmic reticulum—and a single pars tuberalis gonadotroph among pars tuberalis thyrotrophs (**B**).

up to the median eminence. A few gonadotrophs and somatotrophs can also be found in the tuberalis, usually close to the transition zone with the anterior pituitary (Fig. 13.4). The PT TSH-positive cells strongly express melatonin MT1 receptors. Melatonin, secreted in the dark (long photoperiod), controls seasonal fertility in sheep and other mammals via stimulation of the PT thyrotrophs to release factors, unidentified and known as tuberalins but proposed to be TSH. There may be retrograde flow in the portal vessels between the pituitary and hypothalamus, which would allow a means of circulating TSH to act on hypothalamic ependymal cells that, in turn, stimulate GnRH neurons and fertility in times of the year of short day-length. It has been proposed that the PT is the site of a circannual clock,[9] and that the PT thyrotrophs act as a seasonal calendar cell, driving hypothalamic and pituitary endocrine circuits.[10] In sheep, long photoperiods induce the circadian transcription factor BMAL2 in the PT, which activates summer physiology through the eyes absent/TSH pathway.[10]

The Pars Distalis (Anterior Pituitary)

The pars distalis forms the bulk of the pituitary gland (75%). Standard light two-dimensional microscopy methods show that the pars distalis consists of clusters (also known as acini) of secretory endocrine cells and nongranular cells surrounded by reticulin fibers and an extensive capillary microvasculature. The pars distalis contains five main secretory cell types, each named according to the hormone it principally releases: somatotrophs (growth hormone [GH]), lactotrophs (prolactin [PRL]), corticotrophs (adrenocorticotropic hormone [ACTH]), thyrotrophs (TSH), and gonadotrophs (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]). The distinct "classical" secretory cell types can be identified immunocytochemically or on a basis of their ultrastructural characteristics, which are detailed in Table 13.1. Historically, histologists classified anterior pituitary cells as basophils, acidophils, or chromophobes on a basis of differential histochemical labeling with acidic and basic dyes such as periodic acid–Schiff orange G stain. These histological methods originally revealed the heterogeneity of secretory cells within the anterior lobe. In a normal adult human adenohypophysis, approximately 10% of endocrine cells are basophils, 40% acidophils, and 50% chromophobes. Experimentally, however, this classification has proved confusing, as the staining method is not able to distinguish hormones within specific cell types and is variable across species, and little is known of the basis of the chemical reactions between the dyes and components of the pituitary cells. Therefore, histochemical methods have been largely replaced by hormone antibody immunolabeling methods. There is no nervous innervation of the secretory cells of the anterior pituitary. Each of the secretory cell types has been well studied by transmission electron microscopy and can be distinguished by its secretory granule morphology, size, distribution, and number. Table 13.2 shows the ultrastructural characteristics associated with each of the secretory anterior pituitary cell types and folliculo-stellate cells. The physiology and control of each cell type is summarized later. The hypothalamus provides the major inputs for the control of pituitary hormone secretion, and this is balanced by feedback regulation exerted by circulating hormones signaling the status of peripheral endocrine glands. Superimposed on the control by blood-borne hormones is the intrapituitary, local paracrine and autocrine regulation by more than 100 compounds secreted locally by secretory and folliculo-stellate cells, detailed in Carl Denef's seminal review.[11]

Anterior Pituitary Cell Distribution and Organization in Networks

Conventional histological methods give the impression that anterior pituitary cells are randomly distributed within the acini across the gland. However, there is evidence in different species that the secretory cell types are concentrated in specific areas and organized in three-dimensional (3D) interconnected networks. In the human pituitary, corticotrophs are found to be more concentrated in the medial regions near to the marginal zone, somatotrophs and lactotrophs are found more in the lateral regions, thyrotroph clusters are found more anteriorly, and gonadotrophs are scattered throughout (Fig. 13.5). It is not known what the origin of this organization may be, but it may relate to sequences of cell determination.[12]

Whole-tissue 3D imaging of the mouse anterior pituitary using two-photon microscopy has shown that, in 3D, pituitary cells of the same type ("homotypic") are organized in extensive structured networks[13] similar to those first shown originally for folliculo-stellate cells.[14] Cell networks have also been visualized in the teleost fish. These approaches rely on transgenic models expressing fluorophore-tagged cells, and it is not clear whether similar cell network organization is also the case in larger mammals and the human pituitary. However, modifications in the organization of pituitary cell networks have been shown to occur in different physiological states. The pituitary gland is regarded as highly plastic, and dynamically adjusts throughout life to changing endocrine status, and as such numbers of each cell type vary with puberty, pregnancy, lactation, stress, the menopause, and aging. In most cases it is not clear if changes in pituitary size of networks are the result of increased cell number via trans differentiation of a different cell type, proliferation of existing cells, or differentiation of adult pituitary stem/progenitor cells and/or increased cell size.[15] Although the difference in responsiveness comparing *in vivo* pituitary hormone release to isolated cells *in vitro* has been attributed to the importance of coordination of secretion through an intact cell network, it is also

TABLE 13.2 Ultrastructural Characteristics Associated With Each of the Secretory Anterior Pituitary Cell Types

Cell Type	Hormone released and major role	% Anterior lobe	Secretory granule size (nm)	Granule shape	Distribution of granules
Somatotrophs	GH Postnatal growth and metabolism	45–60	350	Spherical and electron dense	Large numbers, occupy a large proportion of the cytoplasm
Lactotrophs	PRL Lactation	10–15	200–350	Larger granules are irregular in shape, smaller granules are spherical	Throughout cytoplasm
Gonadotrophs	LH and FSH Control of gonads and reproductive function	20	200, 350	Smaller electron-dense granules and larger electron-lucent	Throughout cytoplasm
Corticotrophs	ACTH Stress response, control of adrenal cortex	6–8	100–200	Moderately electron-dense, spherical	Line perimeter of inner plasma membrane
Thyrotrophs	TSH Control of thyroid T3/T4 production	5–6	100–200	Moderately electron-dense, spherical	Throughout cytoplasm
Folliculostellate	Paracrine control, release of mediators e.g., IL6, annexin 1, follistatin	4	-	Cells are agranular	Cells are agranular

Somatotrophs. Somatotrophs produce and secrete GH, a 191–amino acid polypeptide hormone. Somatotrophs are the most numerous cell type in the anterior pituitary and are readily identified by their ultrastructure of the cytoplasm filled with large-diameter electron-dense secretory granules (Fig. 13.6). Somatotrophs were the first of the pituitary cell types to be revealed as a 3D network extending throughout the pituitary by 3D *in vivo* imaging of GH–green fluorescent protein (GFP) mice. The somatotrophs are joined by adherens and gap junctions,[16] which are important for the rapid exchange of signals, such as cyclic adenosine monophosphate (cAMP) and calcium, between cells, and in turn coordinate synchronized secretory responses.[13] The pulsatile secretion of GH is controlled by GH-releasing hormone (GHRH) and somatostatin, which coordinate to generate the episodic circadian pattern of GH release with maximal release during early sleep. GHRH binds to G protein–coupled receptors (GPCRs) coupled to cAMP/protein kinase A/CREB signaling to stimulate exocytosis, whereas somatostatin, a potent inhibitor of GH secretion, binds to SST2 GPCRs that decrease cAMP production.[17] Long-acting analogs of somatostatin are used clinically in conditions of GH excess (see also Chapter 6). The gastrointestinal peptide ghrelin also directly stimulates somatotroph GH release by activation of the growth hormone secretagogue receptor

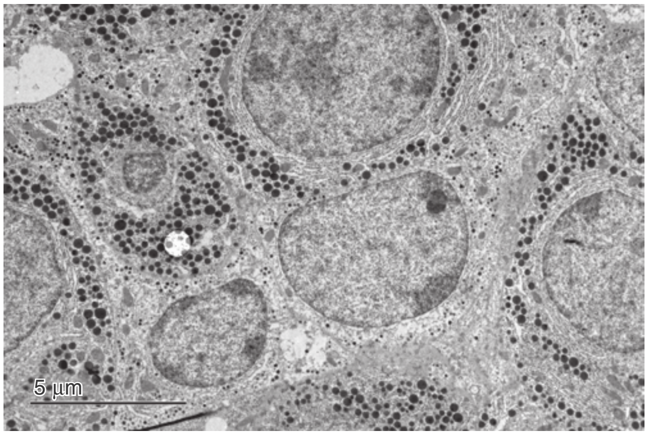

Fig. 13.8 Electron micrograph of a type II lactotroph (mouse).

GHS-R1a,[17] a GPCR that is highly expressed in somatotrophs coupled to the PLC/IP3/calcium signaling pathway. Ghrelin must be acylated by the enzyme ghrelin-O acyl transferase to be functionally active at GHS-R1a receptors. Elevated concentrations of GH in plasma exert "short-loop" negative feedback to inhibit GHRH neurons and stimulate somatostatin neurons, whereas liver-derived insulin-like growth factor (IGF)-1 exerts "long-loop" negative feedback via acting on somatotroph IGF tyrosine kinase receptors to inhibit GH mRNA transcription and GH secretion.[17] GH is important for body growth and metabolic homeostasis and is regulated by many other hormones and nutrients that influence energy expenditure at the hypothalamic and somatotroph level, including glucocorticoids, sex steroids, adiponectin, fatty acids, and leptin (see also Chapter 17). In general, GH concentrations rise in fasting and decline in obesity via the interplay of these regulatory molecules involved in the complex regulation of energy expenditure, and in different physiological contexts such as stress, exercise, and sleep. The circadian pattern of GH release diminishes with aging and is absent in postmenopausal women and men over 50 years.[18]

Lactotrophs. Lactotrophs produce PRL, a 198–amino acid polypeptide. Lactotrophs show a high degree of plasticity with respect to their number and size, particularly in females. Lactotroph number, and subsequent PRL secretion, increase during pregnancy to stimulate breast development in preparation for milk production at lactation. During pregnancy, the pituitary gland may increase in size by approximately 30% owing to lactotroph hyperplasia, which is sustained during lactation but rapidly declines by enhanced apoptosis of lactotrophs to their previous numbers after weaning. In adult rats and mice, there are sex differences in the number of lactotroph cells in the anterior pituitary. Female animals have more lactotroph cells than their male counterparts, and the mitotic activity of lactotroph cells is considerably higher in adult female animals and varies with the estrous cycle. The sex difference in the mouse becomes apparent between 21 days and 35 days of age, which corresponds to the period at which the female mouse ovary begins to secrete estrogens in increasing amounts. There is also an increase in lactotroph number at puberty associated with changes in cell morphology, such that, in adult rodents, the lactotroph population is heterogeneous based on the morphology of their PRL-containing secretory granules. Three types of lactotroph, have been described: type I, or "mature," lactotrophs are polygonal cells that contain irregularly-shaped, large secretory granules with a diameter of 300 to 700 nm (Fig. 13.7); type II, or "intermediate," lactotrophs are oval or polygonal cells that contain spherical granules with a diameter of 100 to 250 nm (Fig. 13.8); type III, or "immature," lactotrophs are oval or polygonal cells that contain small spherical granules with a diameter of 100 nm. Estrogen stimulates the development of the type I morphological subtype of lactotroph in the rat anterior pituitary, such that 80% of lactotrophs are type I in female rats. Estrogen effects on lactotroph cell growth are mediated via induction of several growth factors, such as IGF-1 and epidermal growth factor, but also by downregulation of dopaminergic control (see also Chapter 4).[18]

Lactotroph–lactotroph gap junctional contacts have been shown to underlie lactotroph network functions. Injection of a gap junction permeable dye into lactotrophs of lactating mice revealed passage of dye between lactotrophs by gap junction coupling that was blocked by gap junction blockers.[19] Augmented gap junction transfer of dye between lactotrophs was measured in primiparas and weaned dams compared with nulliparas, and electron microscopic identification of intercellular gap and adherens junctions revealed that the majority of intercellular junctions were between lactotrophs. An increase in homotypic lactotroph–lactotroph intercellular junctions in primiparas compared with nulliparas was observed, showing increased anatomical connectivity that paralleled an increase in the extent of dye transfer, representing functional connectivity. Furthermore, a decrease in junctions between lactotrophs and folliculo-stellate cells was measured in primiparas versus nulliparas, which may reflect a functional reduction in inhibitory mediator signaling via folliculo-stellate cell contacts. Long-lasting plasticity was found to be retained when females experienced further lactations, resulting in improved functional PRL secretion.

The coordination of lactotrophs into an interconnected network is also significant for the coordination of *PRL* gene transcription.[20,21] Studies combining real-time live-cell imaging of *PRL* gene activity in pituitary slices from adult hPRL-GFP rats, and mathematical modeling of the recorded expression patterns have determined how the spatial organization of lactotrophs affect the transcriptional dynamics of the *PRL* gene. Whereas in single lactotrophs the bursts of expression of the *PRL* gene are randomly timed, bursting patterns are coordinated with lactotroph neighbors. The coordination is dependent on gap junction connections and signaling. Mild trypsin treatment of slices reduced expression of the gap junction protein connexin 43 and adherens junction proteins, without tissue disaggregation, resulting in greater intracellular distances between lactotrophs and a decrease in the coordination of *PRL* transcription between closely located lactotrophs. Treatment of slices with gap junction inhibitors reduced the synchronization of transcription activity between neighboring lactotrophs. In developing pituitary glands, the low lactotroph density provides less opportunity for cell junction signaling, and reduced transcriptional coordination occurs between cells compared with in adults.[20] In the embryonic immature lactotroph network, lactotrophs are mainly isolated from each other, with only a small number of cell junctions detected and no transcriptional coordination. Overall, cellular communication between

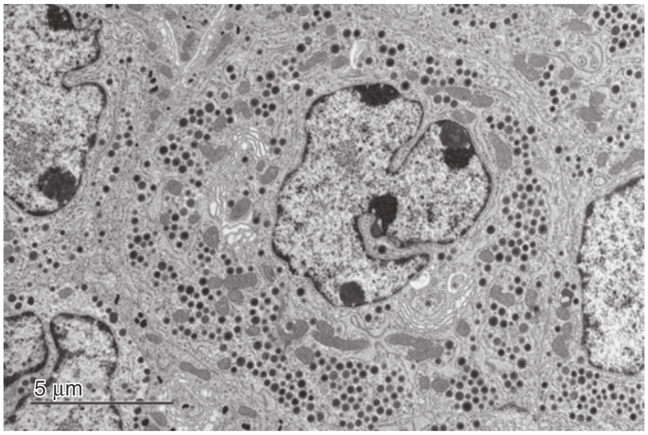

Fig. 13.9 Electron micrograph of a gonadotroph (mouse). The secretory granules have distinctive varying electron density.

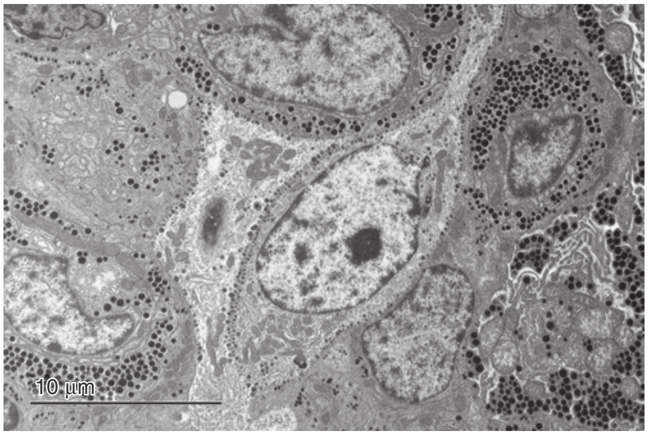

Fig. 13.10 Electron micrograph of two adjacent corticotrophs (mouse). The secretory granules are small and located along the plasma membrane.

lactotrophs is important for the coordination of *PRL* transcription activity, and it would be reasonable to predict that lactotroph transcriptional coordination would be increased during pregnancy and lactation because of the enlargement of the lactotroph cell population.

PRL secretion is pulsatile and episodic, and concentrations rise approximately 60 minutes after sleep onset, with peak plasma concentrations usually in the early hours of the morning at 4:00 AM to 7:00 AM. The tonic hypothalamic control of prolactin is mainly inhibitory, by dopamine[22] acting at the D2R GPCR, which signals to reduce cAMP levels, and therefore prolactin granule exocytosis. Dopamine inhibits PRL secretion from all lactotroph subtypes, but the PRL-releasing factors TRH and vasoactive intestinal peptide stimulate PRL release from type II and III lactotrophs.[23] Although the principal role of PRL is lactation, it has been implicated in a number of functions regarding metabolic homeostasis and roles in the skeleton, in the skin, and parental behaviors in males and females.[24]

Gonadotrophs. The gonadotrophins LH and FSH are synthesized within a single cell type, the gonadotroph. The gonadotrophins consist of a common alpha subunit and a specific beta subunit responsible for conferring biological activity on the heterodimer. All three subunits are encoded by separate genes localized on different chromosomes. Different secretory granule populations have been identified in gonadotrophs of the rat, mouse, and sheep, namely small LH- and secretogranin (SgII)-positive granules; large FSH- and chromogranin A (CgA)-positive granules; and intermediate-sized granules containing an electron-dense LH- and SgII-positive core and an electron-lucent CgA-positive outer region. Gonadotrophs can be distinguished from other anterior pituitary cell types by the variety of secretory granules of different sizes and electron density (Fig. 13.9). How this difference in secretory granule storage relates to different patterns or timing of hormone release is not known. Synthesis and secretion of the gonadotrophins is dependent on the decapeptide GnRH, which is produced within specific hypothalamic neurons. The hypothalamo-pituitary-gonadal (HPG) axis develops embryonically but, apart from short periods of activation immediately after birth, remains suppressed through a combination of gonadal and nongonadal mechanisms until puberty onset.[25] GnRH has long been regarded as the master hormone of the HPG axis, as, in the absence of this, hormone synthesis of LH and FSH is reduced such that mice carrying a mutation in this gene do not reach sexual maturity, but remain prepubertal throughout life (see also Chapters 102 and 103).[4] However, the discovery of kisspeptin stimulation of GnRH via KISS1 receptors on GnRH-expressing neurons revealed an additional level of control to the HPG axis.[25]

Corticotrophs. Corticotrophs secrete ACTH, a 39–amino acid peptide derived from the precursor prohormone POMC, which is released during stress on activation of the hypothalamic-pituitary-adrenal axis. Corticotrophs have a very distinctive morphology in rodents, appearing initially as small round cells and developing to become polygonal or stellate with long cytoplasmic processes known as cytonemes.[26] The secretory granules are small and lined up along the perimeter of the cell close to the plasma membrane (Fig. 13.10; Table 13.2). This organization would suggest that ACTH granules are primed for rapid fusion with the plasma membrane and secretion in response to stress. However, human corticotroph ultrastructure is very different, with round cells containing numerous large (250- to 500-nm diameter) secretory granules distributed throughout the cell. Conventional immunocytochemistry in several species shows that corticotrophs are concentrated around the medial central section of the anterior pituitary, but are also distributed sparsely across the gland. Whole-pituitary 3D imaging in a line of POMC-EGFP transgenic mice has revealed that corticotrophs organize in a connected 3D network that exists in close proximity to gonadotrophs and capillaries.[26]

The primary releasing factors for ACTH secretion are hypothalamic CRH and arginine vasopressin (AVP) released into the portal circulation in response to stress, while glucocorticoids exert negative feedback on ACTH secretion. CRH and AVP act on GPCRs to stimulate ACTH release. CRH stimulates both ACTH release and *POMC* transcription via CRH type 1 (CRHR1) receptors acting through cAMP/protein kinase A/CREB-dependent pathways. CRHR1 receptors are critical for control of ACTH release, as in transgenic mice in which CRHR1 is knocked out there is no ACTH response to stress. AVP acting through the V1b receptor is a weak stimulator of ACTH release administered alone, but potentiates the stimulatory effect of CRH on ACTH release.[27] The signaling mechanism involves V1b receptor activation of the PLC/IP3/DAG/PKC signaling cascade, which (1) increases intracellular calcium release from intracellular stores and (2) stimulates cAMP production in response to CRH via protein kinase C–mediated inhibition of phosphodiesterase activity, increasing the exocytosis of ACTH-containing granules. Pharmacological and receptor knockout approaches indicate that AVP is required for the full ACTH response to acute stress and to sustain responses during chronic stress, but in the absence of AVP the amount of ACTH released is sufficient for a full adrenal glucocorticoid response. During infection and inflammation, cytokines released by immune cells (e.g., interleukin [IL]-1, IL-6)[18] and intrapituitary folliculo-stellate cells (leukemia inhibitory factor, IL-6) also stimulate ACTH production to, in turn, amplify production of the antiinflammatory glucocorticoids.[28] Furthermore, CRH and AVP both act as mitogens and stimulate growth of corticotrophs. CRH and AVP both mediate the increase in corticotroph hyperplasia and hypertrophy that results after adrenalectomy. A lack of negative feedback by adrenal glucocorticoids results in an increase in CRH and AVP expression in paraventricular nucleus neurons, and treatment of rats with V1 receptor antagonists or deletion of V1 receptors in mice blocks the mitogenic response to adrenalectomy.[29] Experiments measuring deoxybromouridine uptake have shown that, after adrenalectomy, the newly-produced corticotrophs originate from undifferentiated cells, and not from the division of existing corticotrophs.[30]

Thyrotrophs. Thyrotrophs secrete the 28-kD glycoprotein TSH and have been the least studied of the anterior pituitary cell types. Thyrotroph ultrastructure is of polygonal cells with numerous small-diameter secretory granules (Table 13.2). TSH is composed of an alpha and beta subunit; the structure of the alpha subunit is the same as in LH and FSH (see also Chapter 65). Thyrotrophs appear sparsely distributed through the pituitary, and it is not known if the cells have a network organization. TSH release is pulsatile and has a diurnal pattern, with a peak at 2:00 AM to 4:00 AM and lower concentrations in plasma in the day.[31] TSH production and release are regulated by the hypothalamic hormones TRH and somatostatin, and by triiodothyronine (T3) and thyroxine (T4) negative feedback. TRH stimulates TSH release by stimulation of TRH type 1 GPCRs on thyrotrophs, which activates the PLC/IP3/calcium/PKC signaling pathway, whereas somatostatin inhibits TSH release by acting at SSTR2 receptors, which reduces intracellular calcium. Feedback inhibition by T3 is by stimulation of nuclear thyroid receptors, which downregulate transcription of TSH subunits. Glucocorticoids[32] and cytokines inhibit TSH production and release by both direct thyrotroph actions and indirect hypothalamic actions, and are responsible for low T3/T4 in sickness. The glucocorticoid diurnal pattern of secretion is thought to regulate in turn the circadian pattern of TSH release.[32] Local control of TSH secretion in the pituitary and of TRH within the median eminence also contributes to control of TSH secretion. TRH acts at TRHR1 receptors on tanycytes at the median eminence,[33] increasing tanycyte endfeet contact with TRH nerve terminals and stimulation of a TRH-degrading ectoenzyme, thereby inhibiting the potential to stimulate TSH. In the anterior pituitary, folliculo-stellate cells express TSH receptors, type 2 deiodinase, and the thyroid hormone transporter MCT8. TSH via folliculo-stellate cells stimulates type 2 deiodinase and local T3 production and induces the secretion of folliculo-stellate cell inhibitors of TSH secretion[34] as a paracrine mechanism that exerts ultra-short-loop feedback control of TSH secretion.

In thyroidectomized rodents in which T3 and T4 negative feedback is removed, dramatic changes in thyrotroph ultrastructure are observed; these altered cells are classically described as "thyroidectomy cells." The thyrotrophs are hypertrophied, and rough endoplasmic reticulum is vastly dilated, occupying most of the cytoplasm (Fig. 13.11), indicating hyperfunction and reduced numbers of secretory granules. Similar thyrotroph thyroidectomy morphology is observed in mice with transgenic deletion of the alpha subunit. As functional TSH is not produced, the lack of T3/T4 results in increased TSH beta subunit synthesis by the secretory pathway.[35]

Folliculo-Stellate Cells. Folliculo-stellate cells form a 3D network throughout the anterior pituitary, with gap and adherent junctions between each other and adjacent endocrine cells. Live imaging first revealed folliculo-stellate cell networks in rat anterior pituitary,[36] and more recently in tilapia fish,[37] using the fluorescent-tagged dipeptide β-Ala-Lys-Ne-AMCA. The dipeptide enters folliculo-stellate cells by peptide transporters and is distributed via gap junctions through the folliculo-stellate network. The connections between folliculo-stellate cells and with surrounding cells suggest functions that could efficiently coordinate changes in the pituitary in response to physiological demands, for example during pregnancy.

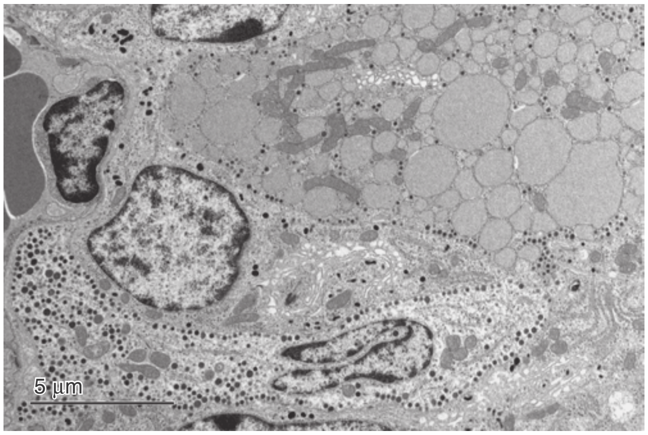

Fig. 13.11 Electron micrograph of a thyrotroph from a thyroidectomised mouse; note the dilated rough endoplasmic reticulum, Golgi apparatus, and mitochondria (a type I lactotroph is below the thyrotroph).

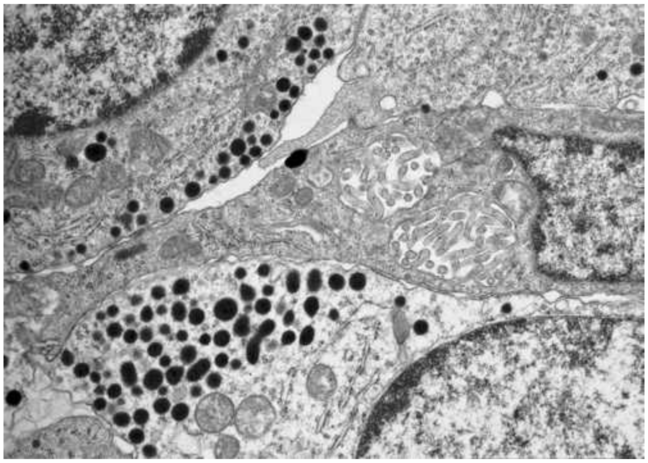

Fig. 13.12 Electron micrograph of a section of a folliculo-stellate cell (rat) forming microvilli-lined follicles.

Folliculo-stellate cells were named based on the fact that, on clustering, the cells formed small follicles (Fig. 13.12) and were highly stellate in structure, with no secretory granules and with sparse rough endoplasmic reticulum or Golgi.[28] Their long cytoplasmic processes facilitate contact via tight junctions with neighboring endocrine cells and interact extensively with perivascular spaces. Marker proteins used to identify folliculo-stellate cells include S100, a calcium-binding protein, and the intermediate filament proteins glial fibrillary acidic protein (GFAP), vimentin, and cytokeratin. Folliculo-stellate cells functionally provide support, protection, and paracrine control of secretion from adjacent endocrine cells via release of factors such as IL-6, annexin 1, and follistatin. Folliculo-stellate cells also regulate the pituitary vasculature, principally through the secretion of vascular endothelial growth factor, which stimulates angiogenesis.[38] Folliculo-stellate cells could therefore play an important part in the coordination of vascular-pituitary plasticity[39] and vascular development.

Pituitary Stem Cells. The presence and identity of pituitary stem cells and their therapeutic potential for regenerative medicine has been one of the most active areas of pituitary research focus in recent years, and is much debated.[40] A large number of studies have provided evidence

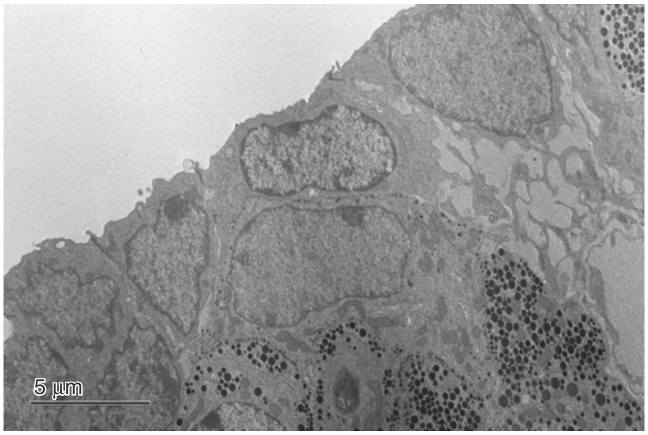

Fig. 13.13 Electron micrograph of marginal cells lining the Rathke's cleft. Note the apical tight junctional complexes and undifferentiated appearance containing few organelles and no secretory granules.

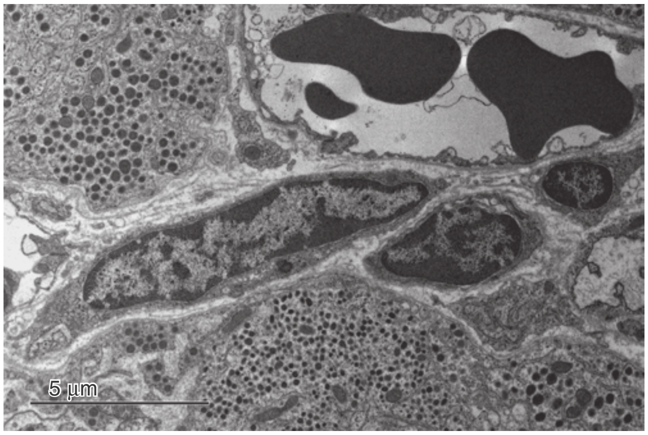

Fig. 13.14 Electron micrograph of three pericytes located in the perivascular space between two capillaries and surrounding secretory cells.

supporting the existence of multipotent stem cells and progenitors in the adult pituitary across species, but their characterization is challenging because of the small number of pituitary stem cells present in adults. Pituitary stem cells express the transcription factor SOX2 and the pituitary transcription factor PROP1, which is necessary to establish the stem cell population and promote an epithelial-to-mesenchymal–like transition, releasing progenitors from the niche.[13] During pituitary embryonic development, proliferating cells are primarily located around the remains of Rathke's cleft. The cleft is retained in adulthood, and the anterior pituitary surface of the cleft is lined with a layer of cells known as the marginal zone.[41] Electron microscopy imaging of the marginal cells (Fig. 13.13) has revealed that they appear undifferentiated, contain sparse organelles, contain no secretory granules, and are joined by intercellular adherens junctional complexes. It has been proposed that marginal cells are stem cells, as they express the classic stem cell markers Nestin, E-cadherin, Sox9, and Sox2,[40] with a similar expression profile and organization in mouse and human.[42] There is also a secondary Sox2- and Sox9-positive population of pituitary stem cells scattered in the anterior pituitary with similar functional features to the marginal cells that is proposed to be a subset of folliculo-stellate cells.[42] Individual pituitary progenitor cells were first shown to be able to produce all anterior pituitary cell types in pituisphere cultures,[43] and pituitary organoids have been successfully grown from Sox2-positive cells.[44] Mouse[45] and human[46] embryonic stem cells have been successfully used to grow 3D pituitary organoids, which are functional with respect to ACTH secretion. In addition, organoids have been grown from induced pluripotent stem cells derived from a patient with congenital hypopituitarism patient with a heterozygous mutation in the orthodenticle homeobox 2 (*OTX2*) gene, providing a powerful human model to be able to identify which step in the development process is not functioning and to study the underlying mechanisms of the disease.[47] Deregulation of pituitary stem cells may result in a tumor-initiating cell population[48] because tumor stem cells have been identified from expression of stem cell markers in pituitary adenomas and other pituitary neoplasms.[49]

KEY POINTS

- The anterior pituitary is situated at the base of the brain in a fold of dura within a boney depression, the sella turcica.
- There are 5 secretory cell types plus, plus folliculo-stellate cells, pericytes and microglia.
- It is connected to the hypothalamus via the portal blood system, which delivers hypothalamic regulators to the pituitary cells.

Finally, normal pituitary structure and function are dependent on the development of the supporting vasculature, yet the molecular detail of pituitary vascular development is not fully known. To date, regenerative pituitary models have focused on secretory cell differentiation and have not reported on blood vessels. In pituitary embryonic development it is not yet clear if development of the vasculature has a direct role in stimulating pituitary cell differentiation.[12] Further characterization of pituitary stem cells in the context of vascular development is required to realize therapeutic potential.

Pericytes. Pericytes are classically described as mural cells located around blood vessels in the perivascular space within the basement membrane and in close proximity to endothelial cells. They are referred to as mural cells because of the presence of contractile fibers that are similar to those found in vascular smooth muscle cells. Pericytes are typically found in the microvasculature, and not in larger vessels. Pericytes typically have a large nucleus with a small amount of cytoplasm and few organelles and extend long cytoplasmic processes within the perivascular space. In the brain, pericytes have been shown to be a critical component of the neurovascular unit, together with endothelial cells and astrocytes, which collectively play an essential role in the maturation and maintenance of the blood-brain barrier. Pericytes have also been well-characterized in the kidney, where they are referred to as mesangial cells, which surround the glomerular capillaries. It has been demonstrated that pericytes play an important role in the separation of vessels into the multiple glomerular capillaries of the renal glomerulus. Pericytes have been shown to be distributed along both the adenohypophysis and neurohypophysis vasculature, and display a phenotype between a fibroblast and a vascular smooth muscle cell. The presence of pericytes in the neurohypophysis was first determined in the 1980s, when pericytes were observed in the perivascular space, and transmission electron microscopy in both the adenohypophysis and neurohypophysis has revealed that pericyte morphology is similar to other organs, with limited cytoplasm and limited numbers of cell organelles. Marker proteins used to distinguish pericytes include desmin and NG2, but these markers are not unique to pericytes. Functional studies in the rat anterior pituitary have shown that pericytes produce components of extracellular matrix type 1 and type III collagen, the collagen-regulating protein fibromodulin, and the TGF-B receptor II. Folliculo-stellate cells produce TGF-B, suggesting that the paracrine control of pericyte collagen synthesis by folliculo-stellate cells is a regulated process. Although pituitary pericytes are found in close proximity to endothelial cells in the pituitary microvasculature, more intimate interactions with endothelial cells in the form of gap junctions and "peg and socket" arrangements have not been observed

(Fig. 13.14). A further network of nongranulated mural cells in the anterior pituitary that express the mural cell marker platelet-derived growth factor receptor beta has been characterized; these cells do not express folliculo-stellate cell markers and are not associated with a perivascular location.[50] The role of this mural cell network requires further characterization.

Pituitary Macrophages. Macrophages of both class M1 and M2 have been identified in the rat anterior pituitary by immunodetection of the respective marker proteins, inducible nitric oxide synthase and mannose receptor. In normal pituitary, both classes are few in number and are distinctively located to perivascular areas.[51] Structural characteristics of pituitary macrophages include heterochromatic nuclei, elongated mitochondria, and large intracellular vesicles lipid droplets and phagolysosomes. M2 macrophages are dramatically increased in number in a rat model of estrogen-induced prolactinoma and may play a role in promoting tumorigenesis.[51] Little is known as to the specific function of macrophages in the pituitary, although their location would render them well-positioned for paracrine communication between the vascular, neuroendocrine, and immune systems.

Coordinated Secretion: Relationship With the Pituitary Vasculature

Recent advances in imaging have revealed more functional details of the coordination of pituitary hormone release, relating particularly to the interrelationships of hypothalamic nerve endings and pituitary cells with the vasculature.[39] *In vivo* imaging of the mouse portal system and somatotroph network to study the delivery of the neurohormone GHRH to somatotrophs has shown that GHRH follows specific capillary routes and results in a specific regional regulation of GH release, and not homogeneous activation of the whole pituitary GH network.[16] Capillaries closely line the clusters and chains of cells that form the GH network. Furthermore, gonadotrophs have also been shown to have a dynamic association with capillary boundaries that varies throughout the ovarian cycle.[52] Electron microscopy imaging of somatotroph ultrastructure in pregnant rats has shown that secretory vesicles redistribute to the regions of the plasma membrane adjacent to a capillary[53] compared with nonpregnant control rats, consistent with more granules being primed to support increased basal GH secretion in pregnancy. Together, these general findings have been confirmed by 3D scanning electron microscopy, which has revealed that, where a cell type contacts a capillary wall, secretory granules in that cell are distributed toward the vessel, whereas if a cell is distant from any vasculature, the secretory granules are more evenly distributed throughout the cytoplasm[54]: 70% of anterior pituitary cells were located adjacent to a capillary, whereas 30% were at the center of acini and distant from perivascular regions. 3D scanning electron microscopy is not able to visualize immunolabeling to identify cell types, but the resolution was high enough that cell types could be differentiated on the basis of ultrastructure. The majority of thyrotrophs and lactotrophs were perivascular, but approximately one third of gonadotrophs, somatotrophs, and corticotrophs were isolated in the parenchyma. It is possible that the isolated secretory cells do not significantly contribute to secretory responses, or it may be the case that they do respond, but hormone that is secreted presumably will diffuse more slowly through the extracellular space to reach a capillary. Overall, the regulation of pituitary secretion is dynamic and involves the integration of the control of hypothalamic, vascular, and local pituitary regulators, and advances in imaging technologies will enable further investigation of these relationships.

Posterior Pituitary Gland (Neurohypophysis)

The posterior pituitary comprises the nerve endings of the oxytocin- and vasopressin-producing magnocellular neurons of the hypothalamus, capillaries, and pituicytes. Oxytocin and vasopressin are both 9–amino acid peptides produced from large precursor proteins that undergo extensive posttranslational processing. The hormones are produced in the cell bodies of the neurons, which are located in the supraoptic and paraventricular nuclei, and are rapidly transported in association with neurophysin along the unmyelinated axons within the hypothalamo-hypophysial tract comprising the pituitary stalk (Fig. 13.15). In the posterior pituitary, each axon branches into several thousand neurosecretory axon swellings (known as “Herring bodies”) and terminals that are packed with oxytocin- or vasopressin-containing dense-cored granules. It has been estimated that each magnocellular neuron contains 10 million secretory granules.[55] Vasopressin maintains body fluid balance and blood pressure by activation of renal V2 receptors (GPCRs coupled to cAMP/PKA/CREB) to increase water reabsorption via insertion of aquaporin water channels, and when blood volume/pressure is decreased, by activation of vascular smooth muscle V1 receptors (GPCRs) coupled to the PLC/IP3/calcium/PKC cascade to cause vasoconstriction (see also Chapter 12).[55] Oxytocin triggers uterine contractions during birth and milk ejection during lactation [55] via oxytocin GPCRs coupled to the PLC/IP3/calcium/PKC cascade, initiating, respectively uterine smooth muscle contractions and contraction of myoepithelial cells in the mammary ducts of the breast. Magnocellular cell bodies are depolarized by stimuli (e.g., dehydration, increased plasma osmolality, suckling) that propagate action potentials, which in turn depolarize the nerve terminals, at which point calcium channels open and intracellular calcium increases, promoting exocytosis of the granules. The axon terminals are closely associated with fenestrated capillaries, allowing the released oxytocin and vasopressin to diffuse across the perivascular space into the bloodstream. Pituicytes are a type of glial cell related to astrocytes that are distributed throughout the pituitary stalk and posterior pituitary (Fig. 13.15). Their role is to support the nerve terminals in clearing local metabolites and ions and in exerting local control of secretion.[56] Pituicytes express the marker protein GFAP, as well as receptors for several neuromodulatory factors such as atrial natriuretic peptide, opioids, and dopamine. The spatial relationship between pituicyte cytoplasmic processes and nerve terminals, including neuroglial synaptoid contacts, plays a modulatory role in the release of oxytocin and vasopressin.[57] When increased peptide secretion is required to meet physiological demands, (e.g., dehydration or lactation) the pituicytes rapidly withdraw their processes from around neurosecretory terminals to allow more ready access of secreted peptide to the circulation. This plasticity in the pituicyte neurovascular spatial relationships and regulation of secretion through morphological changes is similar to tanycyte plasticity in the median eminence and PT follicular cell remodeling with photoperiod.[9]

KEY POINTS

- The posterior pituitary is an outgrowth from the brain which makes close contact with the anterior pituitary.
- Its principal hormones, secreted from the nerve terminals, are vasopressin and oxytocin.
- Its blood supply is via the inferior hypophyseal artery, a branch of the internal carotid artery.

CONCLUSIONS AND FUTURE DIRECTIONS

The hypothalamus and pituitary gland unit has numerous regulatory and homeostatic roles and provides the pivotal means of communication between the brain and peripheral endocrine systems. There have been many advances in our understanding of the functional importance of the organization of pituitary cells in recent years. Ongoing areas of neuroendocrine research will provide a greater understanding of the plasticity between neuro-glial-vascular-pituitary cell networks in different physiological states. 3D-view serial block face scanning electron microscopy[58] is one technique that could resolve the question of whether a 3D pituitary cell network organization is evident in the human pituitary, and would require high-quality tissue preservation and ultrastructural resolution to allow morphological identification of cell types. With growing understanding of the importance of homotypic cell connections and functional interactions between pituitary cells, questions remain as to the integration of communication between secretory cells in networks via gap junctions and paracrine control via mediators released in the extracellular space. Finally, further knowledge of the factors required for pituitary organogenesis will be important for refining the use of pituitary stem cells as therapeutic tools for hypopituitarism and understanding stem cell involvement in pituitary adenoma development.

Conclusion, 222

INTRODUCTION

The vast majority of pituitary tumors (PTs) are represented by neuroendocrine tumors (NETs) arising from the endocrine cells of the anterior pituitary, also referred to as pituitary adenomas (PAs) or pituitary NETs. Most PTs occur sporadically without identifiable predisposing genetic factors, whereas, in some 5% of cases, PTs arise in a familial setting. Familial PTs can develop as part of a syndromic condition, such as multiple endocrine neoplasia type 1 (MEN1), multiple endocrine neoplasia type 4 (MEN4), Carney complex (CNC), McCune-Albright syndrome (MAS), pheochromocytoma/paraganglioma with pituitary adenomas (*3P* associations, 3PAs), DICER1, and Lynch syndromes. However, as seen in the case of familial isolated pituitary adenoma (FIPA), pituitary adenomas can occur in the absence of other manifestations, as is the case for patients harboring mutations in the aryl hydrocarbon receptor-interacting protein (*AIP*) gene and in patients with X-linked acrogigantism (XLAG). Nevertheless, in the majority of FIPA families, the causative genetic mutations still remain to be identified.

Owing to either incomplete penetrance or the occurrence of *de novo* mutations, mutations in genes associated with PT development can also be identified in patients without a family history of PTs, especially in those with early-onset disease. A genetic diagnosis is particularly relevant in these patients, as it allows cascade genetic testing and the identification of seemingly unaffected carrier family members who can benefit from an early diagnosis and treatment or, in the case of syndromic diseases, allow screening for other manifestations in the proband.

In this chapter, we will discuss the genetic and clinical aspects of familial and sporadic PTs, focusing on germline and somatic mosaic mutations causing FIPA and syndromic conditions predisposing to PTs, including MEN1, MEN4, CNC, MAS, 3PAs, DICER1, and Lynch syndrome (summarized in Table 14.1).

FAMILIAL ISOLATED PITUITARY ADENOMA

FIPA is characterized by the occurrence of PTs in two or more members of the same family without other associated clinical manifestations.[1] It is estimated to account for around 2% to 4% of all PTs.[2] FIPA is a heterogeneous condition and includes families with the same PT subtype (homogeneous FIPA) or families whose members develop different subtypes of PTs (heterogeneous FIPA). Most homogeneous FIPA families harbor somatotrophinomas or prolactinomas, followed by nonfunctioning pituitary adenomas (NFPAs) and, rarely, corticotrophinomas, whereas in heterogeneous FIPA all possible combinations of different PT subtypes can be observed, the most common being the association of somatotrophinomas and prolactinomas. Most FIPA cases have no known genetic cause, whereas *AIP* mutations[3] can be identified in 10% of FIPA families.[4] As a consequence of incomplete penetrance, *AIP* mutations can also occur in subjects with apparently sporadic early-onset somatotrophinomas or prolactinomas.[5-7] The other well-established FIPA-related genetic abnormality is the duplication of the *GPR101* gene at Xq26.3, identified in patients with infant-onset gigantism.[8] Most of the described XLAG patients presented as isolated cases because of *de novo* germline or somatic mosaic mutations, and only three cases of familial XLAG have been reported so far.[8,9] Examples of different FIPA kindreds are shown in Fig. 14.1.

KEY POINTS

- FIPA is defined by the occurrence of PTs in two or more family members in the absence of other clinical manifestations. Two genes, *AIP* and *GPR101* are known to cause FIPA. Nonetheless, in the majority of FIPA families, the causative genes remain to be identified.

AIP-Related Familial Isolated Pituitary Adenoma

Mutations in the *AIP* gene (11q13.2) are identified in 10% of FIPA cases and 2% to 28% (depending on age at presentation and PT subtype) of

TABLE 14.1 **Germline and Somatic Mosaic Mutations Causing Pituitary Tumors**

Syndrome	Gene and Inheritance Pattern	Germline or Somatic Mosaic	Penetrance for Pituitary Disease	Main Clinical Characteristics
FIPA	*AIP* (AD)	Germline	15%–30%	Early-onset (typically in the second decade) somatotrophinomas or mixed somatotroph-lactotroph tumors and prolactinomas. Mutations in 10% of FIPA families and up to 20% of early-onset PTs (typically causing gigantism or early-onset acromegaly)
	GPR101 (X-linked)	Germline or somatic mosaic in males with sporadic disease	100%	Early-onset (<2 years) gigantism
MEN1	*MEN1* (AD)	Germline or rarely somatic mosaic	30%–40%	Hyperparathyroidism, PTs (mostly prolactinomas and NFPAs), GEP NETs, other neoplasms
MEN4	*CDKN1B* (AD)	Germline	Incomplete (% unknown)	MEN1-like phenotype
Carney complex	*PRKAR1A* (AD)	Germline	10% symptomatic acromegaly, 70% GH excess	Skin pigmented lesions, cardiac and cutaneous myxomas, multiple nonendocrine and endocrine neoplasms including pituitary hyperplasia and PTs (mostly somatotrophinomas and prolactinomas or mixed, very rarely corticotrophinomas)
	Unknown gene (2p16)	Germline	Unknown	Same as for PRKAR1A
	PRKACB	Germline	Unknown	Described in one patient with typical CNC phenotype[63]
McCune–Albright syndrome	*GNAS* (not inheritable)	Somatic mosaic	20%	Café-au-lait spots, polyostotic fibrous dysplasia, precocious puberty, GH excess in about 20% of patients
Pheochromocytoma/ paraganglioma with pituitary adenoma	*SDHA, SDHB, SDHC, SDHD, SDHAF2, MAX (AD)*	Germline	<1%	PPGL, RCC, rarely GIST; rarely PTs (prolactinomas, somatotrophinomas, and NFPAs); one case of pituitary carcinoma reported
DICER1 syndrome	*DICER1* (AD)	Germline or somatic mosaic	<1%	Multiple malignant and benign tumors. Rarely, early-onset pituitary blastomas (ACTH-secreting)
Lynch syndrome	*MSH2, MLH1, MHS6, PMS2, EPCAM (AD)*	Germline	<1%	Multiple cancers (more commonly colorectal and endometrial). Rarely, adult-onset PTs (including two reported pituitary carcinomas)

ACTH, adrenocorticotropic hormone; *AD*, autosomal dominant; *CNC*, Carney complex; *FIPA*, familial isolated pituitary adenoma; *GEP NET*, gastroenteropancreatic neuroendocrine tumor; *GH*, growth hormone; *GIST*, gastrointestinal stromal tumor; *MEN1*, multiple endocrine neoplasia type 1; *MEN4*, multiple endocrine neoplasia type 4; *NFPA*, nonfunctioning pituitary adenoma; *PPGL*, pheochromocytoma and paraganglioma; *PT*, pituitary tumor; *RCC*, renal cell carcinoma.

patients with early-onset sporadic PTs.[4,10] The disease penetrance in *AIP* mutation carriers is typically incomplete. Studies of large families show a penetrance of 15% to 30%. PTs in *AIP* mutation carriers arise at a younger age, presenting clinically in most cases between the second and third decades of life, are more often macroadenomas, and are frequently larger and more invasive compared to *AIP* mutation–negative PTs.[6,11-13] A male preponderance has been described in most studies,[4,12,14] although this could be potentially explained by an ascertainment bias because of the prevalent inclusion of patients with gigantism, a condition occurring more commonly in males.[15] The vast majority (80%) of *AIP*-related PTs are represented by growth hormone (GH)-secreting tumors (somatotrophinomas or mixed somatotroph-lactotroph PTs), followed by prolactinomas (10%–15%).[16] Clinically-presenting NFPAs are rare, accounting for approximately 5% of cases.[12,13] NFPAs are often found to express GH or prolactin on immunohistochemistry. A single case of a thyrotroph PT has been described, while no corticotrophinomas have been identified to date in patients with pathogenic *AIP* mutations. In our cohort, 44% of *AIP*-related PTs manifest clinically with pituitary gigantism, a manifestation of GH excess starting at an early age, before the closure of the growth plates[4] (Fig. 14.2A). Conversely, *AIP* mutations are identified in approximately 40% of patients with nonsyndromic gigantism (28% among those with sporadic disease and 65% of patients from FIPA families).[4] Typically, clinically-presenting *AIP*-related PTs are diagnosed as invasive macroadenomas (Fig. 14.2E–F). Pituitary apoplexy is relatively frequent (~8%–10% of all cases) and can be the presenting feature of the disease (Fig. 14.2E). *AIP*-related somatotrophinomas are often resistant to first-generation somatostatin analogs (SSAs),[12,14] and their management frequently requires a multimodal approach including surgery, radiotherapy, and/or use of the GH receptor antagonist pegvisomant to reduce insulin-like growth factor 1 (IGF-1) levels and prevent the detrimental consequences of GH excess.[17] Data on the use of the multireceptor ligand pasireotide are limited but suggest potential beneficial effects.[18] Prolactinomas in *AIP* mutation carriers are prevalently macroadenomas and are often resistant or partially resistant to medical treatment with dopamine agonists.[12,19]

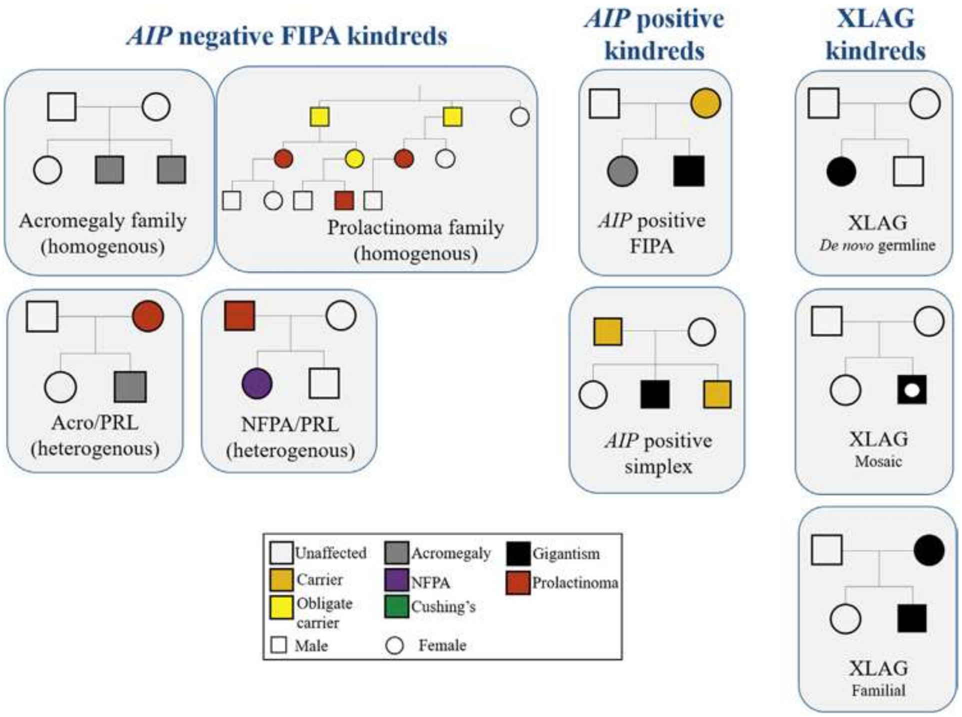

Fig. 14.1 Family trees showing typical examples of various types of familial isolated pituitary adenoma (*FIPA*) kindreds. Different combinations of pituitary tumors can be observed in *AIP* mutation–negative families. Owing to incomplete penetrance, *AIP* mutation–positive families include FIPA kindreds with two or more affected patients or simplex cases without a family history of pituitary tumors. Most X-linked acrogigantism (*XLAG*) patients are simplex cases with females carrying *de novo* germline mutations and males having somatic mosaic mutations. *NFPA,* Nonfunctioning pituitary adenoma; *PRL,* prolactinoma.

Following the identification of an *AIP* mutation, cascade genetic screening should be offered to all individuals at risk. This is particularly relevant because PTs can be diagnosed in approximately 10% of seemingly unaffected carriers, with about half of these patients having previously unrecognized GH excess.[4] Owing to an early diagnosis, treatment outcomes in these patients are generally more favorable compared with clinically presenting PTs. However, it should be noted that screening of clinically unaffected *AIP* mutation carriers can identify microadenomas in some cases, without apparent hormone excess.[4] These are somewhat similar to those identified in *MEN1* mutation carriers[20] and may represent incidentalomas occurring in the general population.

Over 100 different mutations have been identified in the *AIP* gene,[1,4] including nonsense, missense, frameshift, splicing, and promoter mutations, deletions, insertions, and segmental duplications. Approximately 70% of these mutations are truncating and lead to the loss of the C-terminal end of *AIP* as a consequence of either nonsense or frameshift mutations resulting in premature stop codons. The most common *AIP* pathogenic variant is the nonsense p.R304* mutation occurring at a CpG hotspot site: a founder effect secondary to this specific *AIP* mutation, as well as other hotspot mutations, has been described in several populations.[3,21,22] Large deletions account for approximately 5% of all mutations but can only be identified with dedicated techniques, such as multiplex ligation-dependent probe amplification. Most *AIP* mutations are inherited, and *de novo* mutations have been very rarely described.

AIP is a cochaperone with several interacting partners, including members of the heat shock protein family, growth factor receptors, nuclear receptors, and viral proteins. The protumorigenic effects of *AIP* mutations depend on the loss of its tumor suppressor function. *AIP* mutations, in fact, result in most cases in the premature truncation of the coding sequence (nonsense and frameshift mutation) or in unstable proteins with a reduced half-life (missense mutations or segmental duplications).[22,23] Moreover, loss of heterozygosity (LOH) at the AIP locus is often found in AIP-related PTs, confirming that tumorigenesis depends on the loss of functional copies of AIP within the tumor cells. The mechanisms linking loss of AIP with PT development remain to be fully elucidated but are likely to be multifactorial and include, among others, enhanced cyclic AMP (cAMP)-dependent protein kinase A (PKA) signaling[24] and downregulation of the inhibitory $G\alpha_{i\text{-}2}$ protein[24] and of the tumor suppressor ZAC1.[25] Alteration of the RET apoptotic pathway has been recently described as a tumorigenic mechanism.[26] Transcriptome analysis of *AIP*-related PTs revealed upregulation of specific cytokines with increased macrophage infiltration, highlighting changes in the tumor microenvironment as factors contributing to the invasive behavior of *AIP*-related PTs.[27]

KEY POINTS

- *AIP* mutations are identified in approximately 10% of FIPA cases and up to 28% of patients with sporadic gigantism or young-onset acromegaly. Penetrance is typically incomplete.

X-Linked Acrogigantism

XLAG is a condition of infant-onset pituitary gigantism secondary to the germline or somatic mosaic duplication of the *GPR101* gene (Xq26.3).[8,28,29] XLAG patients present significant GH excess, in most cases with concomitant hyperprolactinemia, caused by mixed somatotroph-lactotroph tumors associated, in some patients, with pituitary hyperplasia. A minority of patients present with hyperplasia in the absence of a PT. XLAG is very rare, with only 34 confirmed cases described so far.[8,9,28,30-34] Unlike other forms of gigantism, XLAG is characterized by a female preponderance. Some 25 of the 34 reported XLAG patients are females carrying germline duplications, whereas somatic mosaic mutations have been identified in the only four reported cases

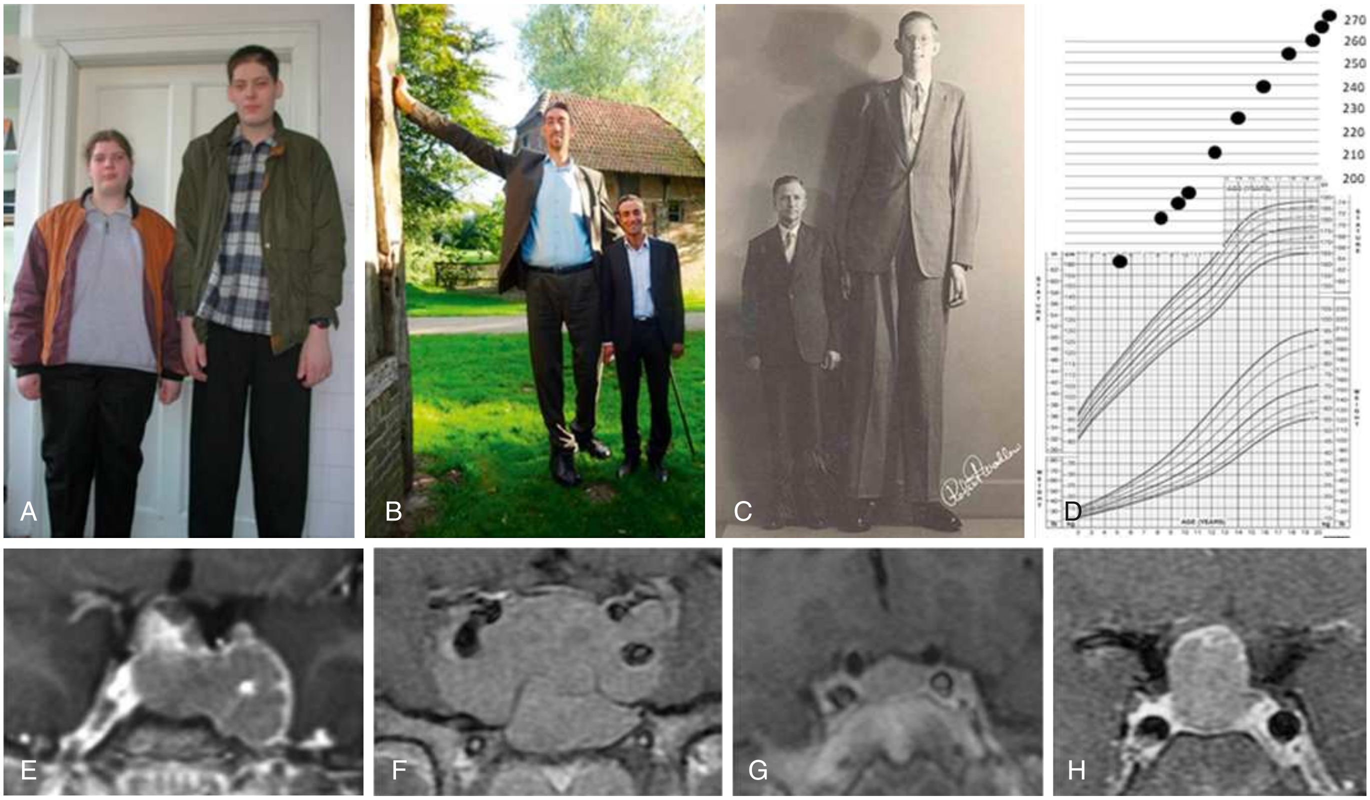

Fig. 14.2 Clinical and radiological features of pituitary gigantism secondary to *AIP* and *GPR101* mutations. **A,** Siblings with whole *AIP* gene deletion. The female patient was diagnosed and treated at the age of 10 years when she was 175 cm (5 ft 8.9 in), while her brother was diagnosed and treated at the age of 21 years when 210 cm (6 ft 10.7 in) (Prof. Vera Popovic's patients). **B–D,** X-linked acrogigantism (XLAG) can lead to extreme tall stature if not treated successfully. **B,** An affected patient (height 251 cm, 8 ft 2.8 in) is shown here next to an unaffected family member (picture kindly provided by Prof. Wouter de Herder, Erasmus MC, Rotterdam). **C–D,** Based on the clinical phenotype, Robert Wadlow, the Alton Giant, is likely to have suffered from XLAG. His birth weight was normal, but he immediately started growing at a rapid rate, and by 6 months of age his weight was 14 kg (30.9 lbs; 50th centile of a 2 year and 10 month old child). He received no treatment, reached a final height of 272 cm (8 ft 11.1 in), and died at the age of 28 years following an infection. Based on the detailed description provided by Behrens in 1932,[148] his sella turcica measured 2.5 cm, suggesting the presence of a pituitary tumor (**B–D** modified from Iacovazzo D & Korbonits M. Gigantism: X-linked acrogigantism and *GPR101* mutations. *Growth Horm IGF Res.* 2016;30-31:64-69). **E–F,** Clinically-presenting pituitary tumors in *AIP* mutation carriers are often macroadenomas with cavernous sinus invasion. Apoplexy (**E**, modified from Dutta P, Reddy KS, Rai A, et al. Surgery, octreotide, temozolomide, bevacizumab, radiotherapy, and pegvisomant treatment of an *AIP* mutation-positive child. *J Clin Endocrinol Metab.* 2019;104:3539-3544.) occurs in approximately 8% to 10% of cases. **G–H,** Examples of the radiological findings in patients with XLAG, including isolated pituitary hyperplasia (G) and a pituitary macroadenoma without evidence of cavernous sinus invasion (H).

of male patients with sporadic disease. In three independent families, mother-to-son transmission has been described, in all instances with full penetrance. As no other clinical manifestations have been described in these patients, XLAG is considered to be a rare cause of FIPA.

XLAG is characterized by the early onset of accelerated growth, in most cases during the first 2 years of life. Other frequently observed manifestations include acral enlargement, coarse facial features, increased appetite, and, less frequently, acanthosis nigricans, sleep apnea/snoring, and hyperhidrosis. Treatment of XLAG patients is often challenging, and, in the absence of prompt treatment, the disease results in markedly increased stature (Fig, 14.2B–D). The radiological features are variable and range from mild pituitary gland enlargement in patients with isolated hyperplasia (Fig. 14.2G) to macroadenomas (Fig. 14.2H), which only rarely show invasive features. Although radical surgery, often resulting in hypopituitarism, can provide control of the disease in some cases, several patients required a combination of surgery, radiotherapy, and medical treatment. SSAs, especially in treatment-naïve patients, are generally ineffective, whereas pegvisomant may prove effective in normalizing IGF-1 levels and growth velocity, allowing the achievement of a normal height in cases with timely diagnosis and prompt initiation of treatment. Hyperprolactinemia in XLAG patients is generally responsive to dopamine agonists.

Most XLAG patients harbor microduplications of Xq26.3 (spanning a region of about 500 kb) involving *GPR101* as well as three other neighboring genes. However, one patient with a typical clinical phenotype was found to have a complex genomic rearrangement with two duplicated regions separated by a normal copy number segment. The duplication in this patient allowed researchers to narrow down the genomic region shared by all patients to an area encompassing solely (in its entirety) the *GPR101* gene, confirming its pathogenic role.[28] Small duplications and low-level mosaicism can be missed by standard chromosome microarrays, and either gene dosage analysis by means of digital PCR or a high-resolution array should be employed when testing for XLAG. Testing of tumor-derived DNA should also be considered when suspecting a somatic mosaic mutation.

The *GPR101* gene encodes an orphan G-protein coupled receptor. In mice, *Gpr101* was found to be expressed primarily in the central nervous system, and particularly in the hypothalamus and amygdala.[35] In humans, *GPR101* is highly expressed at the mRNA level in the nucleus accumbens, as well as in the medulla and the occipital lobe.[36] Although *GPR101* is significantly overexpressed in the PTs of XLAG patients, it is not expressed in sporadic somatotrophinomas or in the normal adult pituitary gland.[8] The mechanisms underlying the pathogenesis of XLAG remain to be defined. GPR101 is coupled to the G-stimulatory protein and is constitutively active.[8,35] The activation of the cAMP-PKA pathway resulting from the overexpression of *GPR101* could potentially underlie the development of pituitary hyperplasia and PTs in XLAG patients. However, the high level of *GPR101* expression in the hypothalamus, and especially in the arcuate nucleus, suggests that this receptor could also potentially play a role in the hypothalamic regulation of GH secretion. Recently, GPR101 was identified as the receptor mediating the antiinflammatory actions of the lipid mediator Resolvin D5 in leukocytes.[37] However, the role of this lipid mediator in the GH axis has not been investigated as yet.

KEY POINTS

- XLAG is a rare condition of infant-onset gigantism caused by the duplication of the *GPR101* gene. Penetrance is complete and all patients develop accelerated growth starting during the first two years of life.

Genetically-Undetermined Familial Isolated Pituitary Adenoma

In most (90%) FIPA families, no causative genetic mutations are identified. Age at disease onset in these patients is comparable to that in patients with sporadic PTs, and both homogeneous (more commonly somatotrophinomas followed by prolactinomas and NFPAs) and heterogeneous (all possible combinations with somatotrophinomas/prolactinomas and somatotroph/NFPAs being the most common) combinations can be observed. Prospectively diagnosed PTs have been described in genetically-undetermined FIPA families, confirming the presence of inheritable predisposing genetic mutations. However, considering the relatively high frequency of PTs in the general population, it is possible that the occurrence of PTs in some of these families could be coincidental.

SYNDROMIC PITUITARY TUMORS

Multiple Endocrine Neoplasia Type 1

MEN1 is an autosomal dominant tumor predisposition syndrome characterized by the occurrence of primary hyperparathyroidism (in >90% of patients by the age of 50 years), gastroenteropancreatic NETs (in ~60% of patients) and PTs (30%–40% of cases) (see also Chapter 133). The prevalence is estimated between 1:10,000 and 1:100,000. Other endocrine and nonendocrine tumors may also occur, such as bronchial and thymic NETs, facial angiofibromas, lipomas, collagenomas, meningiomas, ependymomas, adrenal adenomas, breast cancer and, rarely, pheochromocytomas.[38-40] In 90% of cases, MEN1 is caused by heterozygous mutations in the *MEN1* gene (11q13). Most mutations are inherited, whereas *de novo* germline or mosaic mutations occur in approximately 10% of patients.

PTs occur in approximately 30% to 40% of MEN1 patients and represent the first manifestation of the disease in about 15% to 30% of cases. PTs are more commonly diagnosed in female patients. Prolactinomas are the most common clinically presenting PT subtype in MEN1 (40%–60%), followed by NFPAs (15%–40%), somatotrophinomas (5%–10%), and, rarely, corticotrophinomas or thyrotrophinomas. It should be noted that GH excess in the setting of MEN1 can be secondary to the ectopic secretion of GH-releasing hormone (GHRH) by NETs, most commonly pancreatic. PTs in MEN1 are frequently macroadenomas, they arise at a younger age compared with sporadic PTs, and, in rare instances, they can be multiple. With radiological screening, indolent, clinically nonfunctioning PTs have also been identified.[20] Responsiveness of prolactinomas to dopamine agonists is variable, and in some series they were found to be more often resistant to medical treatment compared with those arising in subjects without MEN1.[41] Considering that PTs may represent the first disease manifestation and the possibility of *de novo* mutations, screening for MEN1 should be considered in patients with childhood-onset pituitary macroadenomas, especially prolactinomas, even in the absence of a personal or family history of MEN1-related disorders, as a relatively high frequency (6%) of *MEN1* mutations has been found in patients with childhood-onset sporadic PTs.[7]

To date, more than 1500 *MEN1* mutations have been described.[42,43] Most of these are represented by frameshift, missense, and nonsense mutations distributed throughout the whole gene. A clear correlation between genotype and risk of PTs has not been demonstrated. *MEN1* is a tumor suppressor gene located on the long arm of chromosome 11 (11q13). LOH at this locus is identified in the vast majority of MEN1-related tumors. *MEN1* encodes a protein named menin, a scaffold protein involved in several cellular processes, including transcriptional regulation, genome stability, cell division, and proliferation.[38] Menin serves as a molecular adaptor to allow the interaction between the mixed lineage leukemia (MLL) protein and the transcriptional coactivator lens epithelium-derived growth factor, which is needed for the association of the MLL complex with chromatin and the expression of MLL target genes.[44] Menin recruits MLL to the promoters of the cyclin-dependent kinase inhibitor 1B (*CDKN1B*) and 1C (*CDKN1C*)[45,46] genes, promoting the transcription of these genes, which encode, respectively, p27 and p57. Loss of these tumor suppressors, which are predominantly expressed in endocrine tissues, might explain the high frequency of endocrine neoplasms in patients with MEN1.

KEY POINTS

- PTs occur in approximately 30-40% of MEN1 patients and include predominantly prolactinomas, NFPAs and somatotrophinomas.

Multiple Endocrine Neoplasia Type 4

MEN4 is a rare condition caused by mutations in the *CDKN1B* gene (12p13) encoding the tumor suppressor p27 (see also Chapter 134). The clinical manifestations generally overlap those of MEN1, with most reported subjects developing primary hyperparathyroidism and, less often, pituitary tumors or other NETs. MEN4 accounts for approximately 2% of *MEN1* mutation–negative MEN cases. To date, 47 cases have been reported.[47-49] Among these, 14 patients developed PTs, including five corticotrophinomas, four somatotrophinomas, four NFPAs, and one prolactinoma. It should be noted that, in the case of two *AIP* mutation–negative FIPA families harboring two distinct *CDKN1B* variants,[50] for one of the identified variants, segregation with the PT phenotype could not be assessed, whereas for the second, only one of the two affected family members carried the variant, therefore rendering it an unlikely cause of the familial PT. Most patients were diagnosed with PTs as adults. However, one patient presented with gigantism caused by a somatotrophinoma diagnosed at the age of five years,[51] and pathogenic *CDKN1B* variants have been recently identified in a small percentage of patients with sporadic childhood-onset Cushing disease,[49] suggesting that sequencing for *CDKN1B* should be considered in these patients. These data also suggest that, in families with known mutations, screening for PTs should start at an early age.

The *CDKN1B* mutations reported so far include frameshift, nonsense, and missense mutations, as well as 5’ untranslated region mutations leading to reduced p27 expression. Considering the rarity of the condition, the exact penetrance and potential genotype–phenotype correlations remain to be established.

KEY POINTS

- MEN4 is a rare autosomal dominant multiple endocrine neoplasia syndrome whose manifestations overlap those of MEN1. Rarely, PTs have been described in the setting of MEN4.

Carney Complex

CNC is a rare autosomal dominant condition characterized by pigmented lesions of the skin, cardiac and cutaneous myxomas, and multiple nonendocrine and endocrine neoplasms, including pituitary hyperplasia and PTs.[52] About two-thirds of patients present elevation of GH or IGF-1 levels, often with concomitant hyperprolactinemia, although symptomatic acromegaly occurs only in about 10% of cases, usually by the third decade of life, presenting clinically with acromegaly or, less frequently, gigantism.[53,54] Most patients with GH excess present with pituitary hyperplasia, typically affecting the somatolactotroph cells expressing both GH and prolactin, which can be accompanied, in some patients, by one or multiple tumors. Most PTs observed in CNC are somatotroph or mixed somatotroph-lactotroph microadenomas,[55,56] although large macroadenomas have also been described. Although most cases of Cushing syndrome in CNC patients are adrenocorticotropic hormone (ACTH)-independent, ACTH-dependent Cushing disease has been reported in two patients carrying a *PRKAR1A* mutation.[57,58] In both cases, LOH in the corticotrophinoma was shown, supporting a direct pathogenic role of the *PRKAR1A* mutation. Among the endocrine manifestations occurring in CNC patients, the most common is ACTH-independent Cushing syndrome owing to primary pigmented nodular adrenocortical disease, which is observed in about 25% of CNC patients.[59] Other endocrine manifestations include testicular tumors, especially large-cell calcifying Sertoli cell tumors, observed in about one third of affected males, thyroid nodules (mostly follicular adenomas), which occur in up to 75% of CNC patients, and, occasionally, differentiated thyroid cancer.

Approximately 70% of CNC cases are secondary to heterozygous inactivating mutations in the *PRKAR1A* gene (17q24.2), coding for the regulatory subunit type 1 alpha of PKA. To date, over 125 *PRKAR1A* mutations have been described,[53] most of which are represented by nonsense and frameshift mutations. In most cases, the predicted mutant proteins are *not* produced as a result of mRNA nonsense-mediated decay. Large deletions can be identified in about 20% of cases where *PRKAR1A* mutations cannot be detected by Sanger sequencing and are often associated with a more severe phenotype.[60] Approximately 70% of cases occur in a familial setting, whereas 30% present as sporadic cases because of *de novo* mutations. *PRKAR1A* acts as a tumor suppressor gene, as confirmed by the frequent finding of LOH in tumors associated with CNC. Loss of PRKAR1A leads to increased PKA activity resulting from the unopposed activation of the catalytic subunits of PKA. The mechanisms linking increased PKA activity with tumor formation remain to be fully established but are likely to involve multiple signaling pathways and include upregulation of D cyclins and activation of the mammalian target of rapamycin pathway.[61,62]

A single case of CNC was described in a patient with a chromosomal triplication affecting the *PRKACB* gene (1p31.1) encoding the catalytic subunit beta of PKA.[63] This patient presented at the age of 19 years with acromegaly, spotty skin hyperpigmentation, and multiple myxomas. A second genetic locus at 2p16 has been associated with CNC; however, the causative gene is still unknown.[64]

KEY POINTS

- Carney complex is a rare autosomal dominant syndrome characterized by multiple endocrine and nonendocrine neoplasms. Approximately 10% of patients present with symptomatic GH excess.

McCune–Albright Syndrome

Somatic mutations in the *GNAS* gene (20q13.32), encoding the stimulatory G protein Gsα, represent the most common recurrent mutation occurring in somatotrophinomas.[65,66] These activating missense mutations occur at either one of two residues: Arg201 or, more rarely, Gln227. Mutations at these sites determine loss of GTPase activity with constitutive activation of the cAMP-dependent PKA, resulting in increased proliferation in cAMP-responsive tissue, including the pituitary gland. When these mutations occur at an early postzygotic stage of development, the resulting somatic mosaicism underlies a rare syndromic condition known as MAS. MAS has an estimated prevalence between 1:100,000 and 1:1,000,000[67] and is characterized by polyostotic fibrous dysplasia, café-au-lait skin macules, and several endocrine manifestations, including precocious puberty (especially in females), hyperthyroidism, testicular lesions (Leydig and/or Sertoli cell hyperplasia), GH excess, and, more rarely, neonatal hypercortisolism. The chances of detecting a *GNAS* mutation by standard PCR are higher in affected tissues, while they are low in leukocyte-derived DNA, especially in patients with only one clinical manifestation. However, the detection rate in leukocyte-derived DNA can be improved by high-sensitivity sequencing using digital PCR.[68] The *GNAS* gene is paternally imprinted in the pituitary gland, and most PTs occur in patients harboring the mutation on the maternal allele.[69,70]

Approximately 10% to 20% of patients present with GH excess[71] associated, in about 80% of affected cases, with hyperprolactinemia. PTs (more commonly macroadenomas) can be identified in 30% to 50% of affected patients, with the remaining patients developing pituitary hyperplasia without a PT. In a group of over 100 MAS patients with GH excess, the mean age of onset was 24 years.[71] Although a significant proportion of patients present clinically with accelerated growth, the final stature is often normal, most likely as a consequence of the high prevalence of associated precocious puberty and increased sex steroid levels. Surgery is often challenging in MAS patients because of fibrous dysplasia affecting the skull base and is only rarely curative. The use of radiotherapy is controversial.[71,72] SSAs can induce control of the acromegaly in only 30% of cases, whereas pegvisomant has been shown to be effective in normalizing IGF-1 levels in most MAS patients in whom it has been employed.[71-73]

KEY POINTS

- MAS is a rare condition secondary to somatic mosaic *GNAS* mutations. Multiple endocrine conditions can occur, including GH excess in approximately 10% to 20% of affected patients.

Pheochromocytoma/Paraganglioma With Pituitary Adenoma

Germline heterozygous mutations in genes encoding succinate dehydrogenase subunits (*SDHx*) and the succinate dehydrogenase (SDH) complex assembly factor 2 protein (*SDHAF2*) represent a cause of hereditary pheochromocytoma and paraganglioma (PPGL) (see also Chapter 99). Several reports have described the occurrence of PTs in patients with *SDHx* mutations,[74-80] confirming an association of pheochromocytoma/paraganglioma with pituitary adenoma (3PAs). LOH has been shown in some of these cases, strengthening the causal association between *SDHx* mutations and PT development. The pituitary cells in *SDHx* mutation–positive PTs often show intracytoplasmic vacuoles, which could draw attention to a possible germline mutation in these cases.[77]

The penetrance of PTs in patients carrying SDHx mutations is low (<1%).[74-77] Prolactinomas, followed by somatotrophinomas and NFPAs, are the typical tumor types observed. Most patients presented with macroadenomas, often with aggressive behavior, including one case of a hormone-negative, steroidogenic factor 1–positive pituitary carcinoma in a patient carrying an *SDHB* mutation.[80] *SDHx* mutations in patients with isolated sporadic PTs are extremely rare,[76] and sequencing for *SDHx* genes should be reserved for patients with a personal or family history of paraganglioma or pheochromocytoma. It should be noted that, rarely, the association of PTs and pheochromocytomas can occur in the setting of MEN1, or the association of acromegaly or Cushing syndrome with pheochromocytoma could be because of ectopic GHRH, ACTH, or corticotropin-releasing hormone secretion by the pheochromocytoma.

The SDH enzymatic complex is composed of four subunits (SDHA, SDHB, SDHC, and SDHD) and is responsible for the reversible enzymatic conversion of succinate into fumarate within the citric acid cycle. The mechanisms linking loss of SDH function with tumor formation are likely to be multifactorial. Disruption of the SDH complex leads to the accumulation of succinate, with consequent inhibition of prolylhydroxylases leading to stabilization of the hypoxia-inducible factor 1α (HIF1α) and transcription of HIF-responsive genes, including growth factors with oncogenic properties, such as vascular endothelial growth factor and transforming growth factor.[81] Moreover, loss of SDH function is associated with genomic methylation and downregulation of several genes, including tumor suppressors and genes involved in epithelial-mesenchymal transition.[82]

Recently, PTs have been described in patients with pheochromocytomas carrying mutations in *MAX* (14q23.3), one of several genes causing familial PPGL.[83-86] These cases include prolactinomas, somatotrophinomas and a case of acromegaly secondary to ectopic GHRH secretion. Notably, one patient had a family history of acromegaly, although co-segregation could not be investigated. Other neuroendocrine and nonendocrine neoplasms have been described in these kindreds, suggesting that *MAX* might represent a novel multiple endocrine neoplasia gene.

KEY POINTS

- PTs can occur in patients carrying mutations in genes predisposing to the development of pheochromocytomas and paragangliomas. This association has been named pheochromocytoma/paraganglioma with pituitary adenoma (3PAs).

DICER1 Syndrome

The DICER1 syndrome, or pleuropulmonary blastoma–familial tumor and dysplasia syndrome, is a rare autosomal dominant condition caused by heterozygous mutations in the *DICER1* gene (14q32.13).

DICER1 syndrome is characterized by a variety of neoplasms, including pleuropulmonary blastoma, ovarian sex cord-stromal tumors (mostly Sertoli-Leydig cell tumor), cystic nephroma, renal sarcoma, genitourinary embryonal rhabdomyosarcoma, nodular hyperplasia of the thyroid, differentiated thyroid cancer, pituitary blastoma, nasal chondromesenchymal hamartoma, ciliary body medulloepithelioma, and pinealoblastoma.

PTs are rare in the setting of DICER1 syndrome (<1%). These neoplasms have been named pituitary blastomas because their features resemble pituitary embryonic tissue, and they are characterized by an aggressive clinical behavior.[87] These aggressive tumors usually arise in young children (median age at presentation is 8 months, with a range from 7 to 24 months), and they present clinically with severe ACTH-dependent hypercortisolism and, in some cases, ophthalmoplegia and visual disturbances. Pituitary blastomas are fatal in about 40% of cases.[87,88] Of 12 pituitary blastoma patients available for genetic testing, *DICER1* mutations were identified in 11 patients,[88] suggesting that these neoplasms represent a pathognomonic feature of DICER1 syndrome.

DICER1 encodes a cytoplasmic endoribonuclease that is responsible for processing miRNAs, which modulate mRNA expression at the posttranscriptional level. In DICER1 syndrome, a germline loss-of-function mutation (more often represented by a nonsense or frameshift mutation) is generally followed by a second somatic "hit," often involving the RNase IIIb catalytic domain of DICER1.[88,89] Somatic mosaic mutations, most commonly in the RNase IIIb catalytic domain, have been identified in some patients using high-sensitivity sequencing techniques, although no PTs were identified in these patients.[90,91]

KEY POINTS

- A subtype of aggressive, infant-onset ACTH-producing PTs named pituitary blastomas occur in the setting of DICER1 syndrome, a rare autosomal dominant condition caused by mutations in the *DICER1* gene.

Lynch Syndrome

Recently, six cases of PTs have been described in the context of Lynch syndrome,[92-95] an autosomal dominant cancer predisposition syndrome characterized by an increased risk of colon cancer as well as other malignancies. Lynch syndrome is inherited with an autosomal dominant pattern and is caused by heterozygous mutations in the DNA mismatch repair genes (*MSH2*, *MLH1*, *MSH6*, *PMS2*) or the *EPCAM* gene. Of the six reported cases, four were tumors with an aggressive clinical behavior, including three corticotrophinomas (one of which rapidly developed into a pituitary carcinoma) and a poorly-differentiated carcinoma. Notably, loss of expression of DNA mismatch repair proteins was described in three cases with available tissue and LOH at the *MSH2* locus was demonstrated in one case, supporting a pathogenic role for the DNA mismatch repair gene mutations. Although the occurrence of PTs in patients with Lynch syndrome appears to be a very rare event, these tumors seem to represent an aggressive subgroup, and the potential risk of pituitary malignancy should be considered in patients with this condition.

KEY POINTS

- Rarely, PTs including pituitary carcinomas have been described in the setting of Lynch syndrome, a tumor-predisposing conditions caused by mutations in a group of DNA mismatch repair genes.

Neurofibromatosis 1 and Tuberous Sclerosis Complex

Neurofibromatosis 1 (NF1) is an autosomal dominant condition characterized by café-au-lait spots, cutaneous and plexiform neurofibromas, and other manifestations, including brain neoplasms, especially childhood-onset optic gliomas.[96] NF1 occurs with a prevalence of 1:2000 to 1:4000 and is caused by mutations in the *NF1* gene (17q11.2). GH excess manifesting clinically with accelerated growth occurs in approximately 10% of NF1 children with optic gliomas.[97] GH excess in these patients is generally responsive to SSAs and can undergo spontaneous resolution with time. In some patients, GH excess is associated with precocious puberty. The underlying mechanisms are unknown, but, considering that usually no PTs are observed in these patients, hypothalamic dysregulation of somatostatin or GHRH signaling is likely to be involved. PTs, including prolactinomas, somatotrophinomas, silent corticotrophinomas, and NFPAs, have been reported in NF1 patients.[98-105] In one of these cases, LOH at the *NF1* gene locus was ruled out, and the PT was found to harbor a somatic *GNAS* mutation instead.[101] Considering the relatively high frequency of both PTs and NF1 in the general population, the occurrence of PTs in patients with NF1 is likely to represent a coincidental finding.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder characterized by the development of multiple hamartomas in several organs, including the skin, central nervous system, kidneys, heart, eyes, gastrointestinal tract, lung, and bones.[106] It is caused by mutations in either of the two tumor suppressor genes *TSC1* (9q34) and *TSC2* (16p13.3). There are a few reports addressing PTs in TSC patients, including prolactinomas, corticotrophinomas, somatotrophinomas, and NFPAs.[107-112] In one patient carrying a variant of unknown significance in the *TSC2* gene, LOH was not detected, and TSC2 staining was preserved in the tumor cells.[107] It is not clear whether TSC patients are at increased risk of PTs, and, pending future studies, the role of *TSC1* and *TSC2* mutations in the pathogenesis of PTs remains uncertain.

Other Germline Variants Linked With Pituitary Tumor Development

A heterozygous variant in the prolactin receptor *PRLR* gene (5p13.2) was described in three sisters with hyperprolactinemia in the absence of a PT.[113] This variant resulted in loss of receptor signaling with consequent prolactin insensitivity. A more recent study looking at *PRLR* variants in patients with prolactinomas described six germline variants, including four rare ones, in a group of 46 patients. Out of the four rare variants, two were found to be significantly enriched compared to general population databases. Only one of these variants was found to increase prolactin receptor signaling, with upregulation of the PI3K-AKT pathway and increased cell proliferation *in vitro*.[114] However, pathogenic *PRLR* variants were not identified in an independent series of 88 prolactinoma patients.[115] Therefore, the role of *PRLR* variants in the pathogenesis of prolactinomas remains unclear. A further study described potentially pathogenic variants in the *RXRG* (1q23.3) and *TH* (11p15.5) genes, respectively encoding a retinoic acid receptor and tyrosine hydroxylase, in a single prolactinoma FIPA kindred.[116] The significance of these findings remains to be established.

Mutations in the immunoglobulin superfamily member 1 (*IGSF1*; Xq25) gene cause an X-linked syndrome of central hypothyroidism, prolactin deficiency, and macroorchidism.[117] Interestingly, male patients with IGSF1 deficiency present increased GH and IGF-1 levels.[118] Acromegalic facial features and increased head circumference are frequently observed in these patients. As these changes occur in the absence of PTs, it is likely that the loss of IGSF1, which is highly expressed in the hypothalamus and in pituitary cells of the POU1F1 lineage, affects the regulation of GH secretion at the hypothalamic or pituitary level.

Heterozygous missense *CDH23* gene (10q22.1) variants have been found to segregate with PTs in three FIPA families.[119] *CDH23* encodes a cadherin member previously implicated in the pathogenesis of a subtype of Usher syndrome, an autosomal recessive condition of hearing impairment, vestibular dysfunction, and retinitis pigmentosa. Potentially pathogenic *CDH23* variants were detected in 15 out of 125 patients with sporadic PTs of different subtypes. The mechanisms as to how *CDH23* mutations could lead to PTs remain unknown, and no functional studies have been performed. It should be noted that Usher syndrome patients or unaffected heterozygous carriers are not known to be at higher risk of developing PTs, and the polymorphic nature of *CDH23* can affect the interpretation of genetic variants in this gene. Hence, future studies will need to confirm the role of *CDH23* in PT development.

Potentially pathogenic missense *CABLES1* (18q11.2) variants were found in four out of 181 patients (2.2%) with Cushing disease.[120] All four patients had corticotroph macroadenomas with high proliferation index. CABLES1 is involved in the negative regulation of cell cycle progression in corticotroph cells in response to glucocorticoids.[121] *CABLES1* knockdown was found to stimulate the growth of a corticotroph cell line.[121] Moreover, CABLES1 protein expression was found to be frequently lost in corticotrophinomas, and this was associated with loss of p27.[121] Although these data support the role of CABLES1 in the pathogenesis of corticotrophinomas, further confirmatory studies will be necessary to assess the frequency of *CABLES1* mutations in patients with Cushing disease, as well as their potential role in the pathogenesis of other PT subtypes.

SOMATIC MUTATIONS IN PITUITARY TUMORS

Somatic mutations in “classical” oncogenes and tumor suppressor genes occur rarely in PTs. For instance, mutations in the *RAS* family of oncogenes have been very rarely described and seem to be limited to pituitary carcinomas and highly aggressive tumors. The most common somatic mutations occurring in PTs are represented by *GNAS* mutations in somatotrophinomas (10%–50%) and *USP8* (30%) mutations in corticotrophinomas. *GNAS*-mutated somatotrophinomas are often smaller, less invasive, and generally better responsive to SSAs compared with nonmutated tumors.[122-124]

Gain-of-function mutations in the deubiquitinase *USP8* (15q21.2) disrupt the interaction between USP8 and the 14-3-3 protein, allowing the cleavage of USP8 and promoting its enzymatic activity.[125,126] This results in increased expression of the epidermal growth factor receptor (EGFR), which promotes corticotroph cell proliferation and ACTH secretion. Somatic *USP8* mutations are associated with smaller tumors and, in some cohorts, they were detected more often in females.[127] Somatostatin receptor subtype 5 (SSTR5) was found to be more highly expressed in *USP8*-mutated tumors, suggesting that these tumors might respond better to pasireotide, a multireceptor SSA with high affinity for SSTR5.[128,129] EGFR inhibitors could potentially play a role in the treatment of *USP8*-mutated corticotrophinomas, and they have been shown to inhibit ACTH secretion *in vitro*.[126] Although virtually all *USP8* mutations are somatic, one patient with Cushing disease and a germline *USP8* mutation was recently described.[130] Notably, this patient had a complex phenotype with, among others, developmental delay, dysmorphic features, and dilated cardiomyopathy.

Mutations in the deubiquitinase gene *USP48* occur in 10% to 20% of *USP8*-wild type corticotrophinomas.[131,132] These mutations result in an increase in USP48 enzymatic activity, with activation of the sonic hedgehog pathway, and promote ACTH secretion in response to corticotrophin-releasing hormone *in vitro*.[132] Similarly to *USP8*, *USP48*-mutated tumors were smaller and had a tendency to occur more frequently in females.

The widespread use of pangenomic techniques has recently provided insights into the role of somatic mutations in the pathogenesis of PTs. Consistent with their low proliferation rate, PTs generally harbor a low number of somatic mutations, and, among these, only a few recurrent mutations have been identified.[65,66,133-136] Although *GNAS* mutations represent the only recurrent somatic mutation in somatotrophinomas, mutations in genes involved in calcium, cAMP, and adenosine triphosphate signaling have been described,[65,66] in keeping with the pivotal role of these pathways in the regulation of GH secretion. Recently, a recurrent hotspot mutation in the *SF3B1* gene has been identified in 20% of a series of prolactinomas investigated using whole-genome sequencing, and these findings were confirmed in an independent validation cohort.[137] The mutation was found to lead to the aberrant splicing of *ESRRG*, a member of the estrogen receptor-related receptor family, leading to increased pituitary-specific positive transcription factor 1 and prolactin expression. The mutation was found to occur more frequently in males and was associated with higher prolactin levels. Further data are needed to confirm these results.

Copy number alterations, including large chromosomal aberrations, occur frequently in PTs, especially in functioning tumors.[134] In corticotrophinomas, genomic instability was associated with larger tumors and a higher invasiveness rate.[138] In somatotrophinomas, chromosomal aberrations were found to occur more frequently in *GNAS* mutation–negative tumors, which were characterized by increased expression of PTTG1, a protein involved in sister chromatin separation and cell division.[139]

Significant advances have been made in the understanding of the driving mutations in craniopharyngiomas, brain tumors arising from remnants of the Rathke's pouch. The majority of adamantinomatous craniopharyngiomas harbor mutations in exon 3 of the *CTNNB1* gene causing activation of the β-catenin signaling pathway.[140] In contrast, the vast majority of papillary craniopharyngiomas harbor the *BRAF* V600E mutation.[141] These findings have therapeutic implications: case reports suggest that BRAF inhibitors can be effective in patients with recurrent *BRAF* V600E–positive craniopharyngiomas, and clinical trials are currently ongoing.[142-144]

CRITERIA FOR GENETIC SCREENING AND CLINICAL MONITORING

Although PTs are relatively common in the general population, only a small proportion of patients develop PTs as the consequence of a germline or mosaic mutation. Therefore, genetic testing is recommended in selected patients, including (1) patients with a family history of PTs, (2) patients with early-onset PTs, and (3) patients with a personal or family history of a syndromic condition known to predispose to PTs. It should be noted that guidelines only exist for the screening of MEN1 patients.[145] For other conditions, recommendations are based on expert opinion and the authors' review of the available evidence.

A detailed family history should be obtained from all PT patients, as it can allow a previously unrecognized history of familial PTs to be uncovered. Although it is possible that dedicated gene panels will become more available in the future, careful clinical phenotyping is highly important, as it can help select patients for genetic screening and guide testing strategies. A proposed algorithm is shown in Fig. 14.3.

Screening for *AIP* mutations should be considered in all FIPA families, as mutations are identified in about 10% of unselected families and 20% of those with familial acromegaly. Owing to the incomplete penetrance, screening for *AIP* mutations should also be considered in patients with early-onset somatotroph or lactotroph macroadenomas. As the vast majority of *AIP*-related PTs present during the second and third decades of life, it is generally recommended to screen all patients with age at onset of 18 years or younger and patients with macroadenomas and age at onset of between 19 and 30 years. The probabilities of identifying an *AIP* mutation vary based on the PT subtype and age at onset and are higher in patients with early-onset somatotrophinomas as about 30% of patients presenting clinically with gigantism harbor an *AIP* mutation. Cascade genetic testing should be offered to relatives at risk, and carriers should be monitored periodically. This is particularly relevant as, despite the low penetrance in these families, early diagnosis of *AIP*-related PTs is associated with improved treatment outcomes.[4] Modalities and the age when screening should start in *AIP* mutation carriers remain to be established, but it is reasonable to monitor growth starting in early childhood (≥3 years) and consider yearly biochemical testing (GH, IGF-1, and prolactin) starting at the age of 10 years.[146] In the absence of abnormalities, baseline pituitary magnetic resonance imaging (MRI) in *AIP* mutation carriers is advised around the age of 10 years and should be repeated every 5 years until the age of 30 years. Adults aged younger than 30 years should undergo a baseline pituitary MRI with yearly clinical and biochemical assessments. As no new diagnoses have been reported in *AIP* mutation carriers with normal biochemical and MRI assessment up to the age of 30 years, the screening frequency can be reduced after the age of 30 years, with consideration to stop screening at the age of 50 years. A proposed strategy for screening and monitoring relatives of *AIP* mutation carriers is summarized in Fig. 14.4.

Because most FIPA families do not have an identifiable genetic mutation, it would be difficult to establish recommendations for the follow-up of family members of *AIP* mutation-negative FIPA families. Penetrance in these families is low, and carriers cannot be identified by genetic screening. Therefore, the probability of diagnosing a PT in apparently unaffected family members is low.

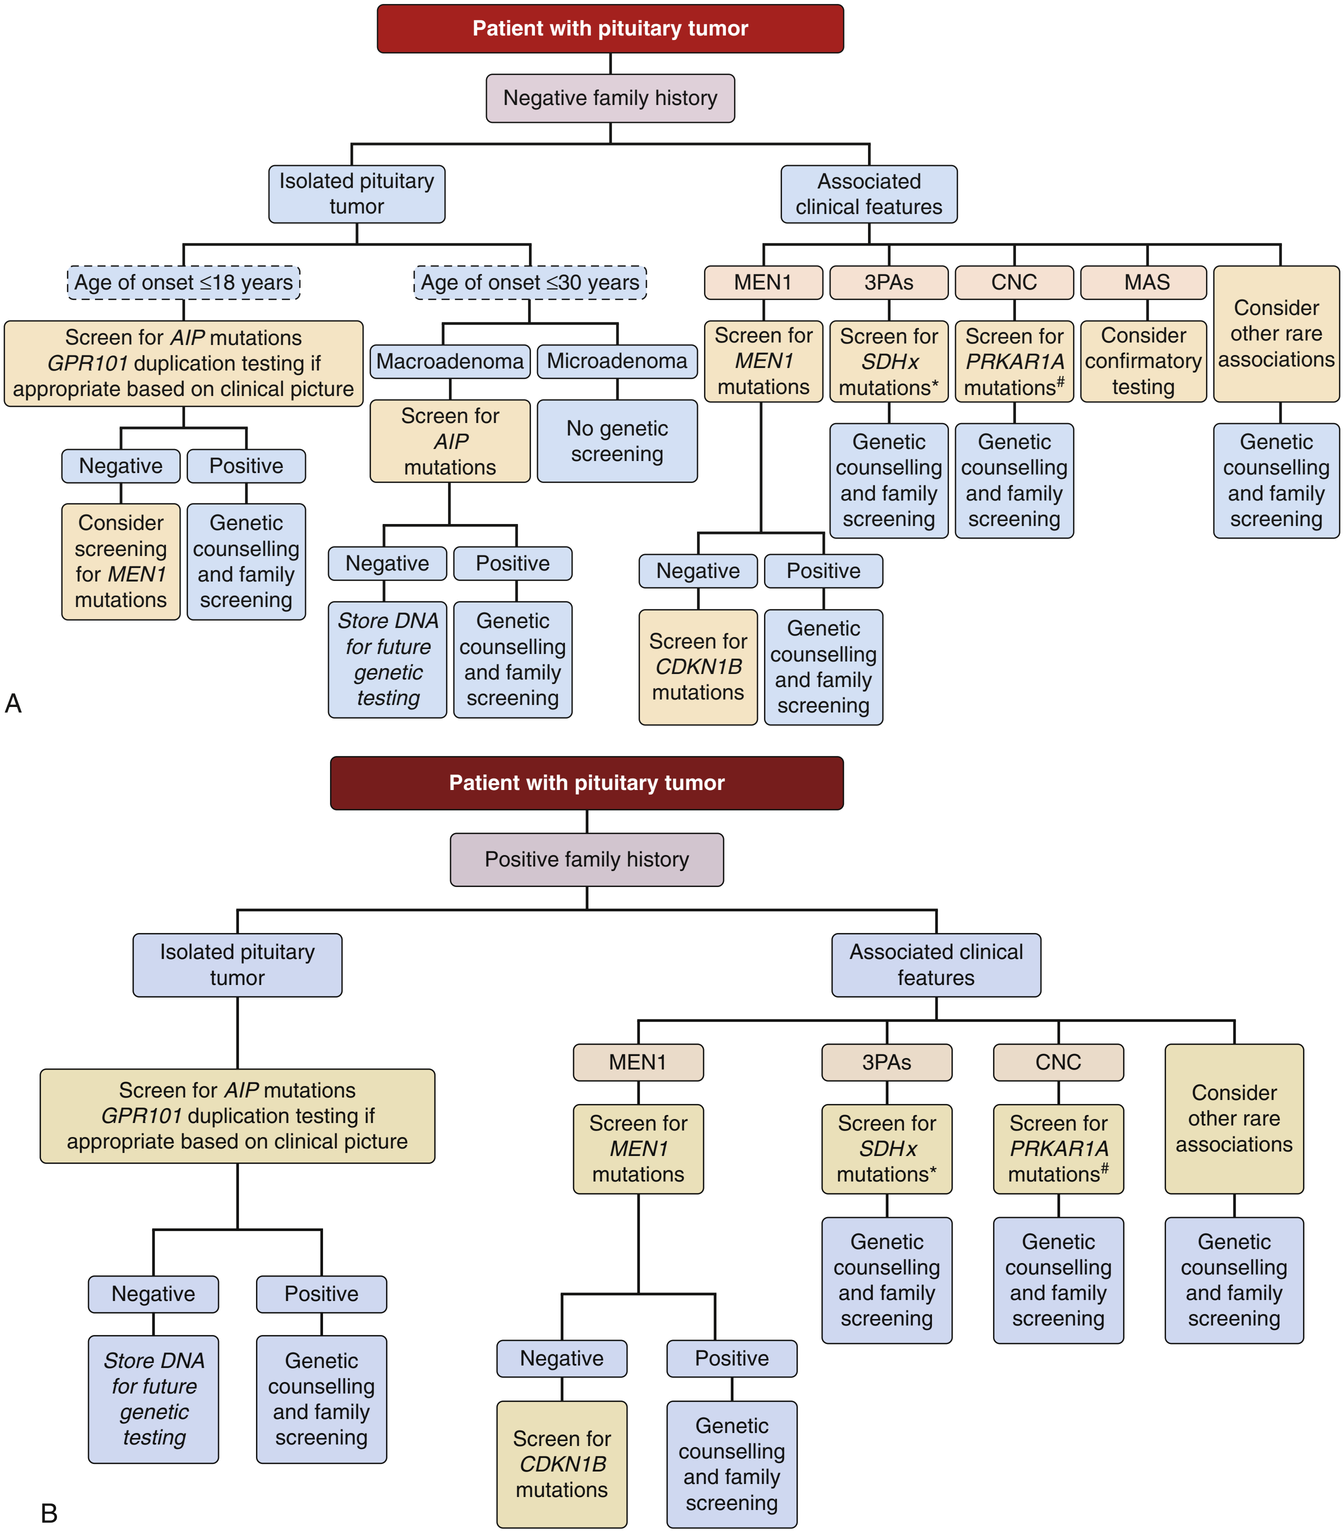
XLAG owing to *GPR101* duplication presents with early-onset gigantism with significant overgrowth starting during the first 2 years of life. A careful evaluation of the timing of the first signs of the disease is important in patients with gigantism, as it can allow the identification of patients who should be tested for XLAG. It should be noted that standard chromosome microarrays might miss smaller or somatic mosaic duplications, and highly sensitive gene dosage techniques, such as digital droplet PCR, should be employed when testing for XLAG. Testing of tumor-derived DNA may be necessary in some cases to confirm a somatic mosaic mutation. XLAG should also be considered in *AIP* mutation-negative FIPA families with X-linked inheritance of early-onset gigantism.

Testing for genes responsible for syndromic conditions should be undertaken in patients with extrapituitary manifestations who fulfill the diagnostic criteria for a specific syndrome and in patients with a family history suggestive of an inheritable syndrome known to predispose to PTs.

Testing for *MEN1* should be considered in patients with a PT in case of a personal or family history of primary hyperparathyroidism and/or gastroenteropancreatic NETs. A negative family history does not rule out the possibility of *MEN1* mutations, as approximately 10% of cases occur as a result of *de novo* mutations. Genetic screening should be extended to relatives at risk, and lifelong clinical and biochemical follow-up should be offered to all mutation carriers. Screening for PTs is advised in children starting at the age of 5 years with annual clinical and biochemical assessments (prolactin and IGF-1). A pituitary MRI should be performed every 3 years.[145] In subjects with a clinical diagnosis of MEN1 who test negative for *MEN1* mutations, the possibility of MEN4 should be considered, and these patients should be tested for *CDKN1B* mutations.

Patients with clinical features in keeping with CNC should be tested for *PRKAR1A* mutations. Such mutations are identified in about 70% of CNC patients. Testing for *PRKACB* amplifications could be considered in the absence of *PRKAR1A* mutations. In patients with a clinical picture suggestive of MAS, a clinical diagnosis is generally made on the basis of the typical manifestations and can be confirmed by *GNAS* sequencing. Because these mutations occur in a mosaic state, the diagnostic yield is low when testing DNA isolated from peripheral blood, although highly sensitive techniques can improve the diagnostic rate. Patients with a personal or family history of paraganglioma or pheochromocytoma should be tested for *SDHx* mutations, and, considering the recently described association with *MAX* gene mutations, *MAX* gene sequencing, including testing for large deletions, could be considered in patients who do not harbor pathogenic mutations in the *SDHx* genes.

Pituitary blastomas represent a pathognomonic feature of DICER1 syndrome, therefore children with these rare tumors should be tested for *DICER1* mutations, and screening should be extended to first-degree relatives. Recommended surveillance strategies for DICER1 syndrome have been recently proposed.[147]



Patient with pituitary tumor

CONCLUSION

Significant advances have been made in the field of pituitary genetics in recent years, and a number of genetic mutations have been associated with an increased risk of developing PTs. Genetically-determined PTs can occur without other associated manifestations as FIPA: so far two genes, *AIP* and very rarely *GPR101*, have been identified to be responsible for this condition, whereas the causative gene(s) in the majority of FIPA families remain to be identified. PTs can also occur as part of syndromic conditions, and, in some cases, they can represent the first manifestation of the disease. Genetically-determined PTs often present at a younger age, can show aggressive behavior with rapid growth and are often resistant to treatment. Although the cost-effectiveness of genetic screening for some conditions is difficult to demonstrate owing to their rarity, the identification of the disease-causing mutations in patients with PTs offers several advantages. Following the identification of a causative mutation, cascade genetic testing allows the identification of carriers who are at increased risk of developing PTs as well as, in the case of syndromic condition, other neoplasms. These subjects will benefit from an early diagnosis as the result of focused monitoring strategies. Moreover, identifying a causative mutation helps inform clinicians of the clinical features of that specific condition, resulting in prompt initiation of effective treatments and earlier diagnosis of associated manifestations. Lastly, the discovery of causative genetic mutations offers the chance to broaden our understanding of the mechanisms underlying PT development.

DEFINITIONS

Pituitary adenomas are tumors that arise from the hormone-expressing cells of the anterior pituitary and are generally considered benign. The majority of these tumors are not clinically relevant, are slow-growing, or are well controlled by surgery and/or medical treatment.

Only a minority of these tumors will give rise to distant metastases, although even in the absence of distant metastasis there are pituitary tumors that escape treatment using any therapeutic strategy. Over the past 10 years, more attention has been given to these not-so-uncommon pituitary tumors, leading to the definition of "aggressive pituitary tumors."

Pituitary Carcinomas

The definition of pituitary carcinoma is simple and well accepted because only a pituitary tumor with craniospinal or systemic metastasis is defined as a pituitary carcinoma. Despite this simple definition, it should be underlined that screening for metastatic disease is mandatory to either confirm or exclude the diagnosis of pituitary carcinoma.[1] Because this screening cannot be performed for all pituitary tumors, the decision to screen should be directed by clinical presentation.[2] The absence of systematic screening for metastasis may lead to an underestimation of the true incidence of pituitary carcinomas. Moreover, a recent case series of pituitary corticotroph carcinomas, which demonstrated the similarity between liver metastases and well-differentiated neuroendocrine tumors of visceral origin,[3] underlined another diagnostic challenge presented by pituitary carcinomas.

> **KEY POINTS**
>
> - Because the clinical definition of pituitary tumor aggressiveness is subject to interpretation, we define "clinically relevant tumor growth" based on signs and symptoms, whereas an "unusually rapid tumor growth rate" is defined as an increase in tumor size of 20% in 12 months or less.

Aggressive Pituitary Tumors

The term "aggressive pituitary tumor" has been used in the past to describe numerous clinical conditions, including giant tumors, invasive tumors, or tumors associated with high levels of hormone secretion. The absence of a clear definition has limited the identification of markers of aggressiveness and the evaluation of therapeutic strategies. In 2018, the European Society of Endocrinology (ESE) guidelines recommended that the diagnosis of an aggressive pituitary tumor be considered in patients with a radiologically-invasive tumor and unusually rapid tumor growth rate, or with clinically relevant tumor growth despite optimal standard therapies (surgery, radiotherapy, and conventional medical treatments).[2] This definition combined clinical and radiological criteria at presentation and tumor behavior during follow-up. It is important to highlight that an invasive pituitary tumor by itself is *not* synonymous with an aggressive tumor. Despite attempts to standardize the definition of an aggressive pituitary tumor, there are still no agreed-upon criteria for "clinically relevant tumor growth" or "unusually rapid tumor growth rate." Therefore, efforts should be made to better evaluate tumor growth and to expand the use of the response evaluation criteria in solid tumors (RECIST) that are used in other tumor types. Recently, Imber et al. demonstrated that the length of the tumor on its longest axis was, in general, adequately correlated to volumetric assessment, suggesting that the use of RECIST classification to evaluate pituitary tumor growth and response to treatment may indeed be appropriate.[4] In our practice, we define an increase in tumor volume of 20% in under 6 months (or 12 months when only annual magnetic resonance imaging [MRI] is available) as an unusually rapid tumor growth rate.

Better defining the criteria for aggressive pituitary tumors will aid in comparing the results of different treatment options but will still not permit the prediction of aggressiveness at diagnosis or enable management to be adapted to the prognosis. To this end, potential pathological and molecular markers associated with pituitary aggressiveness will be discussed in a later section.

EPIDEMIOLOGY

An excellent recent review has addressed the question of the epidemiology of aggressive pituitary tumors.[5] The high prevalence of pituitary tumors at autopsy or in radiological series (average prevalence rates of 14.4% [range 1%–35%] and 22.5% [range 1%–40%], respectively)[6] suggests that most pituitary tumors go unnoticed. According to cross-sectional community-based studies performed in different countries in Europe, the prevalence of clinically significant pituitary tumors ranged from 78 to 115 cases per 100,000 indivdiuals,[7,8] In the absence of strict criteria, the incidence of aggressive pituitary tumors can only be estimated based on the results of surgical series that evaluated the frequency of invasive tumors, postoperative recurrence, and response to standard treatment. Moreover, the incidence of pituitary carcinoma was obtained from large collections of pathology samples (0.13%–0.4%).[9,10] We can argue that, in the absence of systematic screening for metastasis, some carcinomas may have remained undiagnosed; however, this would not significantly change the number, which would still be low. Nevertheless, it is interesting to note that publications describing pituitary carcinomas dramatically increased after the first report of temozolomide (TMZ) treatment for pituitary carcinoma in 2006.[11] Despite these limitations, Dekker et al. estimated that less than 0.1% of all pituitary adenomas that are detected will become malignant, and most likely around 0.5% will display an aggressive course.[5] Although most pituitary tumors are benign and easily managed, we suggest that, as is the case for other rare tumors, aggressive pituitary tumors and pituitary carcinomas should be registered in an international cancer registry specific to pituitary tumors. The paucity of the data obtained from the National Cancer Institute's Surveillance, Epidemiology, and End Results database highlighted the need for a specific registry[12] to identify the true incidence of these tumors, exclude any publication bias, and allow a better characterization of mortality.

Natural History of Pituitary Carcinomas

Although no clinical features can predict the occurrence of pituitary carcinoma, the majority originate from macroadenomas, which are usually invasive into the cavernous sinus and resistant to medical treatment, requiring multiple surgical procedures and radiation therapy. A switch from a clinically nonfunctioning tumor to a functioning tumor seems to be a marker of evolution towards more aggressive behavior or towards metastasis.[13]

In a literature review of all the published cases of pituitary carcinoma from 1947 to 2017, Yoo et al. identified 72 individual cases in papers with full text available for review.[14] In 2017, we published the results of TMZ treatment in a large cohort of patients with tumors that included 14 pituitary carcinomas,[15] whereas the ESE survey, conducted in parallel, included 26 additional individual cases, leading to a total of 112 pituitary carcinoma cases: 65 in men and 47 in women. The median age at diagnosis was 45 years (range 9–75 years), and there was no difference in prevalence according to gender.

Details concerning metastases were available for 86 patients. The median time until identification of metastasis was 7 years, ranging from 0 to 31 years after diagnosis. *De novo* metastases were present in two cases, and the diagnosis was postmortem in three patients. The main locations of metastases were spinal and intracranial, but metastases could also be found in many locations, as seen in other types of cancer (liver, bone, lymph node, lung), and could present as either isolated single lesions or widespread dissemination to multiple organs (Fig. 15.1). Given the latency between primary diagnosis and metastasis, the ESE guidelines recommend screening for metastases in two instances: in the presence of site-specific symptoms (i.e., neurological complaints or neck/back pain) or in cases of discordance between radiological and biochemical findings (i.e., an increase in hormone levels without an increase in apparent tumor volume).[2]

KEY POINTS

- An extensive imaging work-up should be performed in the case of signs and symptoms that are atypical for pituitary tumors (cranial nerve palsies, neck/back pain, etc.) or in cases of discordant biochemical and radiological findings to identify metastases and confirm the diagnosis of pituitary carcinoma.

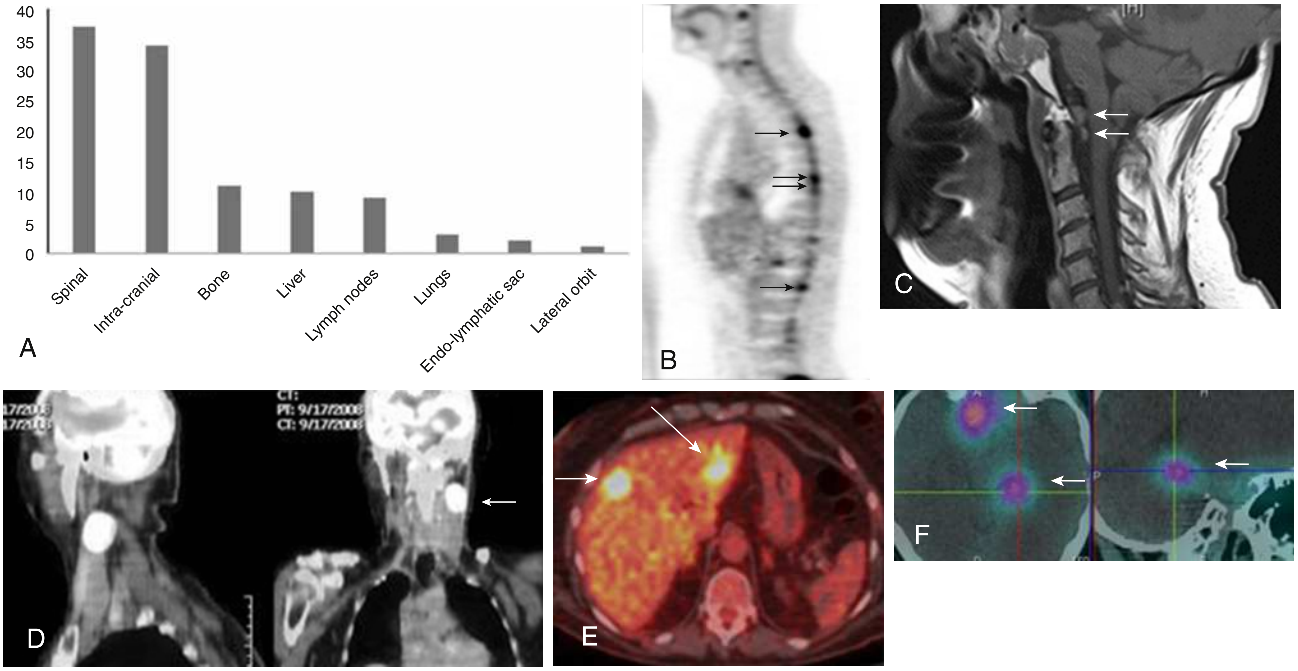

Fig. 15.1 Pituitary carcinoma metastases. **A,** Localization of pituitary carcinoma metastases (available data from 86 published cases). Bone scintigraphy demonstrating multiple vertebral metastases. **C,** T1-weighted sagittal magnetic resonance imaging showing two spinal cord metastases. **D,** Cervical lymph node metastasis on computed tomography (CT) scan. **E,** Liver metastases on (^{18}F)-fluorodeoxyglucose–positron emission tomography/CT. **F,** Brain metastases identified on ^{111}In-pentetreotide scintigraphy. All metastases are indicated by arrows.

Tumors of pituitary-specific transcription factor 1 (Pit1) lineage were found most frequently, representing 42% of all tumor types. Among these, prolactinomas ($n = 30$) were the main type, followed by growth hormone (GH; $n = 12$), and finally rare thyroid-stimulating hormone (TSH; $n = 3$) or TSH-prolactin ($n = 1$) tumors. The second most common lineage, with a similar number of cases, was the T-Pit lineage, with corticotroph tumors representing 40% of cases ($n = 45$). Gonadotroph tumors originating from the SF-1 lineage and hormone-negative tumors represented only 5% and 13% of the tumors, respectively (Fig. 15.2). Of the 112 cases, 52 deaths related to tumor progression were reported at the time of publication (survival status was unavailable for 10 patients).[13,14,15] The time until death was highly variable, from 10 months to 21 years after diagnosis.[14] However, it is noteworthy that, according to recent studies, TMZ treatment seems to improve the overall survival of responders compared with nonresponders.[13,15] For example, Lasolle et al. reported that median survival in patients treated with TMZ was 44 months (95% confidence interval [CI]: 42–infinity) among responders compared with 16 months (95% CI: 9–25) in nonresponders.[15]

PREDICTIVE FACTORS OF AGGRESSIVENESS

Pathological Markers of Aggressiveness

According to the 2017 World Health Organization (WHO) classification, the diagnosis of pituitary carcinoma cannot be made based solely on histopathological analysis; it also requires the identification of craniospinal or systemic metastases.[1] One of the major issues in pituitary pathology is the development of tools that will enable the early recognition of pituitary tumors that will evolve poorly and, most notably, allow the identification of pituitary carcinomas before they metastasize.

Ki-67 Proliferation Index, Mitotic Count, and P53. Taken individually, proliferation markers such as mitotic count and Ki-67–labeling index have failed to reliably identify those pituitary tumors that would later follow an aggressive course.[16,17] The results regarding anti-P53 immunodetection are similar in this respect. In one study, P53 immunoexpression was detected in 15% of invasive pituitary adenomas and in 100% of pituitary carcinomas but was absent in noninvasive pituitary adenomas.[18] Strong and diffuse P53 immunoexpression related to *TP53* mutations has also been described in a few cases of pituitary carcinoma.[19] Conversely, in other studies P53 expression was not found to be associated with recurrence[20] or invasiveness.[21] These inconsistent results regarding the Ki-67–labeling index and P53 immunoexpression may be related to different counting methods, or to technical variability (e.g., antibody clones used, tissue fixation). The "atypical adenoma" diagnostic category, which was first mentioned in 2004 in the WHO classification, does not appear in the more recent 2017 edition.[1] The lack of precise thresholds for assessment of mitotic counts or P53 immunodetection in the definition of atypical adenomas may account for difficulties in reliably identifying this entity in daily practice.[22]

The use of classifications including multiple clinical and pathological parameters has recently emerged as an alternative to a putative universal predictor of aggressiveness for pituitary tumors.[23] This approach is close to the definition of "high-risk adenomas" provided by the WHO classification.[1] High-risk adenomas are clinically aggressive neoplasms defined as rapidly growing, invasive tumors with a high Ki-67 proliferation index.

A clinicopathological classification taking into account pathological markers (mitotic count, Ki-67 proliferation index, P53 immunoexpression) and invasion has produced significant results in predicting the outcome of pituitary adenomas in several studies that included a total of 1470 patients[24-28] (Table 15.1). According to this classification, the risk of recurrence/progression is 3.72 to 12 times higher in grade 2b tumors (invasive and proliferative) (Fig. 15.3 A6, A9, A12) than in grade 1a tumors (noninvasive and nonproliferative).[24,25] Interestingly, pituitary carcinomas are mostly classified as grade 2b tumors.[24,28] In the 2016 ESE survey, it is noteworthy that aggressive pituitary tumors and pituitary carcinomas shared similar clinical and histopathological features.[29]

KEY POINTS

- We recommend the use of a pathological classification taking into account invasion and proliferative markers to identify pituitary tumors with a high risk of recurrence and resistance to medical treatment.

The experts who produced the WHO classification did not endorse any system of prognostic grading but strongly recommended the assessment of invasion and proliferation markers (mitotic count and Ki-67 proliferation index) for pituitary tumors.[1] This is in line with ESE guidelines that recommend at least a histopathological analysis, including hormone and Ki-67 immunodetection, as well as evaluation of P53 immunoexpression and mitotic count when the Ki-67 proliferation index is 3% or higher.[2]

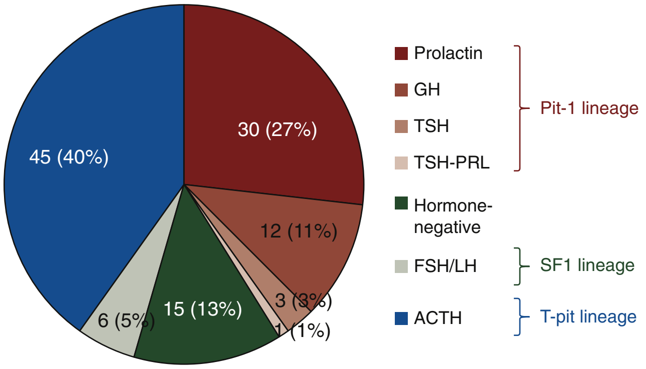

Fig. 15.2 Tumor type according to the lineage of the 112 pituitary carcinomas published in the literature. *ACTH*, adrenocorticotropic hormone; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *LH*, luteinizing hormone; *Pit-1*, pituitary-specific positive transcription factor 1; *PRL*, prolactin; *SF1*, steroidogenic factor 1; *T-pit*, T-box pituitary transcription factor 19; *TSH*, thyroid-stimulating hormone.

TABLE 15.1 French Five-Tiered Clinicopathological Prognostic Classification

Invasion is defined by histological and/or imaging and/or intraoperative evidence of invasion of the cavernous sinus and/or sphenoid sinus.

Proliferation is defined by at least two of the three following criteria:

- Mitotic count greater than two mitoses per 10 high-power fields (HPFs).
- Ki-67 proliferation index greater than or equal to 3%.
- P53 immunopositivity if more than 10 strongly positive nuclei per 10 HPFs.

Invasion	Proliferation		Metastasis +
	NO	YES	
NO	1a	1b	3
YES	2a	2b	

From Trouillas J, Roy P, Sturm N, et al. A new prognostic clinicopathological classification of pituitary adenomas: a multicentric case-control study of 410 patients with 8 years post-operative follow-up. *Acta Neuropathol.* 2013;126:123-135.

TABLE 15.2 Histological Subtypes of Aggressive Pituitary Adenomas According to the 2017 World Health Organization Classification System

Sparsely-granulated somatotroph adenoma
Silent corticotroph adenoma
Crooke cell adenoma
Lactotroph adenoma in men
Pit1-positive plurihormonal adenoma

From Lopes MBS. The 2017 World Health Organization classification of tumors of the pituitary gland: a summary. *Acta Neuropathol.* 2017;134:521-535.

Histotypes. The 2017 WHO classification of pituitary adenomas distinguishes some histopathological variants that may follow a more aggressive course. These include sparsely-granulated (SG) somatotroph adenomas, silent corticotroph adenomas (SCAs), Crooke cell adenomas, lactotroph adenomas in men, and Pit1-positive plurihormonal adenomas (Table 15.2).

Despite the recognition in the WHO classification of these subtypes as aggressive variants of pituitary adenomas, the true prognostic value of these histotypes is still debated in the literature.

Sparsely-Granulated Somatotroph Tumor. SG variants of somatotroph adenomas are defined as GH-producing pituitary neuroendocrine tumors that exhibit a characteristic cytoplasmic globular aggregate of cytokeratins termed a “fibrous body.” The 2017 WHO classification recognizes this variant as an aggressive subtype of pituitary adenoma.[1] However, studies comparing SG somatotroph adenomas with their densely-granulated (DG) counterparts show conflicting results in terms of invasion rate and postoperative outcome. In some studies, invasion was found to be more frequent in SG tumors,[30-32] whereas in others no significant difference was observed.[33,34] In one study, the postoperative remission rate was reported to be lower in SG tumors,[34] whereas no difference was observed in another study.[35] SG somatotroph tumors have also been found to express lower levels of somatostatin receptor (SSTR) 2a[33,36]. This may explain why SG tumors are usually less responsive to somatostatin analogs (SAs) than DG somatotroph adenomas.[33,34,37] This lower response of SG somatotroph tumors to SAs is certainly a contributing factor for their inclusion in the WHO group of aggressive pituitary adenomas.

Crooke Cell Tumor. Crooke cell adenoma is an exceedingly rare subtype of corticotroph tumor.[38] The very low number of cases available for prognostic analysis makes definite conclusions about their aggressiveness difficult. They are composed of neoplastic cells that harbor the typical hyaline ring-like cytoplasmic accumulation of cytokeratins seen in normal corticotrophs of patients with hypercortisolism. In comparison to macroadenomas in Cushing disease, invasion of the cavernous sinus is more frequent, but no significant difference regarding their rate of recurrence has been demonstrated.[38]

Silent Corticotroph Tumor. SCAs are clinically and biochemically nonfunctioning neuroendocrine tumors showing evidence of corticotroph differentiation.[39] Some authors have associated SCA with a poorer prognosis, and the 2017 WHO system classifies these tumors as a subtype of “aggressive” adenoma.[1,40] However, a metaanalysis of cases of SCAs reported up to 2017 did not find any evidence that supported a higher risk of recurrence compared with other nonfunctioning pituitary adenomas.[41] The poorer prognosis that has been suggested by some authors may be explained by the higher prevalence of SCA among the published pituitary carcinomas.[13]

Pituitary-specific positive transcription factor 1–Positive Plurihormonal Tumor. Previously referred to as “silent subtype 3 pituitary adenoma,” this neoplasm was initially defined as a rare ultrastructural entity. In the 2017 WHO classification, this tumor forms part of the Pit1 family.[42] Pit1 (which is encoded by *POU1F1*, or the POU class 1 homeobox 1 gene) is a transcription factor that is specific to the somatotroph, lactotroph, and thyrotroph lineages (Fig. 15.3A5). The clinical spectrum of Pit1-positive plurihormonal adenomas is broad as they may be ‘silent’ or associated with hyperthyroidism, acromegaly, and hyperprolactinemia (Fig. 15.3B). They lack diffuse and strong immunoexpression of Pit1-lineage hormones, showing negative, scattered, or focal immunopositivity for GH and/or prolactin and/or β-TSH (Fig. 15.3A4, A7, A10). The 2017 WHO system classifies this subtype in the group of “aggressive” adenomas.[1] These tumors are frequently large, invasive macroadenomas, with a high rate of residual disease and recurrence/progression (Fig. 15.3C).[42,43] The aggressiveness of this entity should now be confirmed in cohorts in which the tumors have been diagnosed according to the new definition of the 2017 WHO classification (anti-Pit1 immunohistochemistry).

Lactotroph Tumors in Men. In comparison with lactotroph tumors in women, lactotroph tumors in men are larger, more invasive, more often resistant to dopamine agonists, and show a lower level of estrogen receptor-alpha expression, which may be related to a lower degree of differentiation.[44]

Null Cell Adenoma. The 2017 WHO classification defines “null cell adenomas” (NCAs) as pituitary adenomas with neither hormonal expression nor transcription factor positivity.[1] In a study of 31 NCAs, defined according to the 2017 WHO criteria, they were more invasive at presentation and were associated with a shorter progression-free survival compared with gonadotroph adenomas.[45]

Molecular Markers of Aggressiveness

There is currently no independent molecular marker used in routine diagnostic practice that allows a pituitary tumor to be designated as aggressive.[46] The relevance of each molecular marker may also depend on the histological type of pituitary adenoma that is being considered.

Chromosomal alterations are more frequent in functional tumors than in silent tumors.[47] In one cohort of 134 pituitary adenomas, no correlation between chromosomal alterations and aggressiveness was found.[47] Conversely, in one study, loss of 11p was observed in aggressive lactotroph tumors, and an additional loss of 11q in malignant lactotroph tumors.[48]

Recurrent somatic mutations are rare in pituitary adenomas and are mostly restricted to *GNAS* (stimulatory G-protein alpha subunit) mutations in somatotroph tumors and *USP8* (ubiquitin-specific protease 8) mutations in corticotroph tumors. The prognostic value of these genetic alterations is unclear, and they likely do not work as independent factors.

GNAS mutations have not been reported to be more frequent in the aggressive SG subtype of somatotroph tumors than in the DG variant.[33,49,50] However, a metaanalysis suggested that *GNAS* mutational status may be a good predictive factor of response to SAs.[51]

In a study of 60 corticotroph adenomas in patients with clinically active Cushing disease, tumors carrying *USP8* mutations were significantly smaller and associated with a higher rate of surgical remission compared with wild-type *USP8* tumors.[52] However, the higher number of Crooke cell adenomas among the wild-type *USP8* tumors included in this study

Fig. 15.3 Radiological and pathological illustration of a pituitary-specific positive transcription factor 1 (*Pit1*)-positive plurihormonal tumor. **A,** Preoperative (1) and postoperative (2) coronal T1 gadolinium magnetic resonance imaging (MRI) of the pituitary tumor. Hematoxylin and eosin (H&E) staining of the pituitary tumor (3). Immunohistochemistry of pituitary hormones: growth hormone (4), prolactin (7), thyroid-stimulating hormone (10); transcription factors: Pit-1 (5), t-Pit (8); SF1 (11), mitotic count on H&E (per 10 high power fields) (6). Immunohistochemistry of the Ki-67 proliferative marker (9) and p53 (12). **B,** Prolactin levels during follow-up of the 24-year-old patient before surgery and after cabergoline and radiation therapy. **C,** Radiological postoperative follow-up of the residual tumor on coronal T2 and T1 gadolinium MRI. The tumor is outlined by the dashed line. Note the tumor shrinkage after radiation therapy. *Cab,* Cabergoline; *GH*, growth hormone; *PRL,* prolactin; *SF1,* steroidogenic factor 1; *TSH*, thyroid-stimulating hormone.

may have contributed to these differences. Conversely, in another cohort of patients with Cushing disease, the prognosis for corticotroph tumors with *USP8* mutations showed earlier and more frequent recurrence.[53]

In their systematic review, Yang and colleagues highlighted the role of several factors in the molecular pathogenesis of pituitary carcinomas.[54] Factors that were upregulated included, notably, vascular endothelial growth factor (VEGF), a key factor in angiogenesis, matrix metalloproteinase 9, an enzyme involved in the degradation of the extracellular matrix and tumor cell migration, and cyclin D1, a protein that, in association with Cdk4 and Cdk6, promotes the G1-S cell cycle phase transition. Downregulated factors included cell cycle inhibitors such as P16ink4a and P27kip1.

TREATMENT

Temozolomide

TMZ is a second-generation alkylating agent that induces DNA damage through attachment of a methyl group to guanine bases. The O6-methylguanine (O6-MeG) lesions are responsible for the majority of TMZ cytotoxicity. The DNA mismatch repair (MMR) pathway that is activated by the mispairing cannot repair the O6-MeG lesion, which ultimately activates apoptosis.[55] An endogenous DNA repair enzyme, O6-MeG-DNA methyltransferase (MGMT), potentially counteracts the cytotoxic effects of TMZ by removing added methyl groups.

Standard therapy with TMZ begins with a dose of 150 mg/m^2 daily for 5 days every 28 days for one cycle; for subsequent cycles, the dose is increased to 200 mg/m^2, depending on patient tolerance, as recommended by the ESE guidelines. In some circumstances, when the maximal dose of radiation therapy has not been reached, a Stupp protocol combining radiotherapy and TMZ at a daily dose of 75 mg/m^2 for 6 weeks, followed by 6 to 12 months (or longer) of "standard therapy," may be used.[2,56]

Since the first reports in 2006,[11,57] numerous case reports and case series have been published, but the largest to date reported the results of a survey conducted by the ESE that included 40 pituitary carcinomas and 125 aggressive pituitary tumors.[13] Although initial publications only reported successful cases, thus introducing a positive reporting bias[58] the larger series[15,59-61] and the ESE survey[13] confirmed that approximately 40% of patients showed a partial or complete radiological response to TMZ, whereas one-third were stable, and the other third showed progression despite treatment. In addition to the radiological response, the biochemical response was also evaluated: 19% presented a complete biochemical response, 34% a partial response, 27% stable disease, and 21% progressive disease.[62] All of the studies were consistent, demonstrating that early response to TMZ (after 3 cycles) was the best predictor of long-term control (Fig. 15.4), whereas no delayed response has been reported to our knowledge. The data were sparse at the time of the publication of the ESE guidelines; however, the results from the ESE survey suggested that those patients who received concomitant radiotherapy (the Stupp protocol) showed an increased response rate (complete or partial radiological response in 71% of cases) compared with those on the standard TMZ treatment schedule. This difference could be attributed to a selection bias, but this possibility should be discussed in the future as an option in

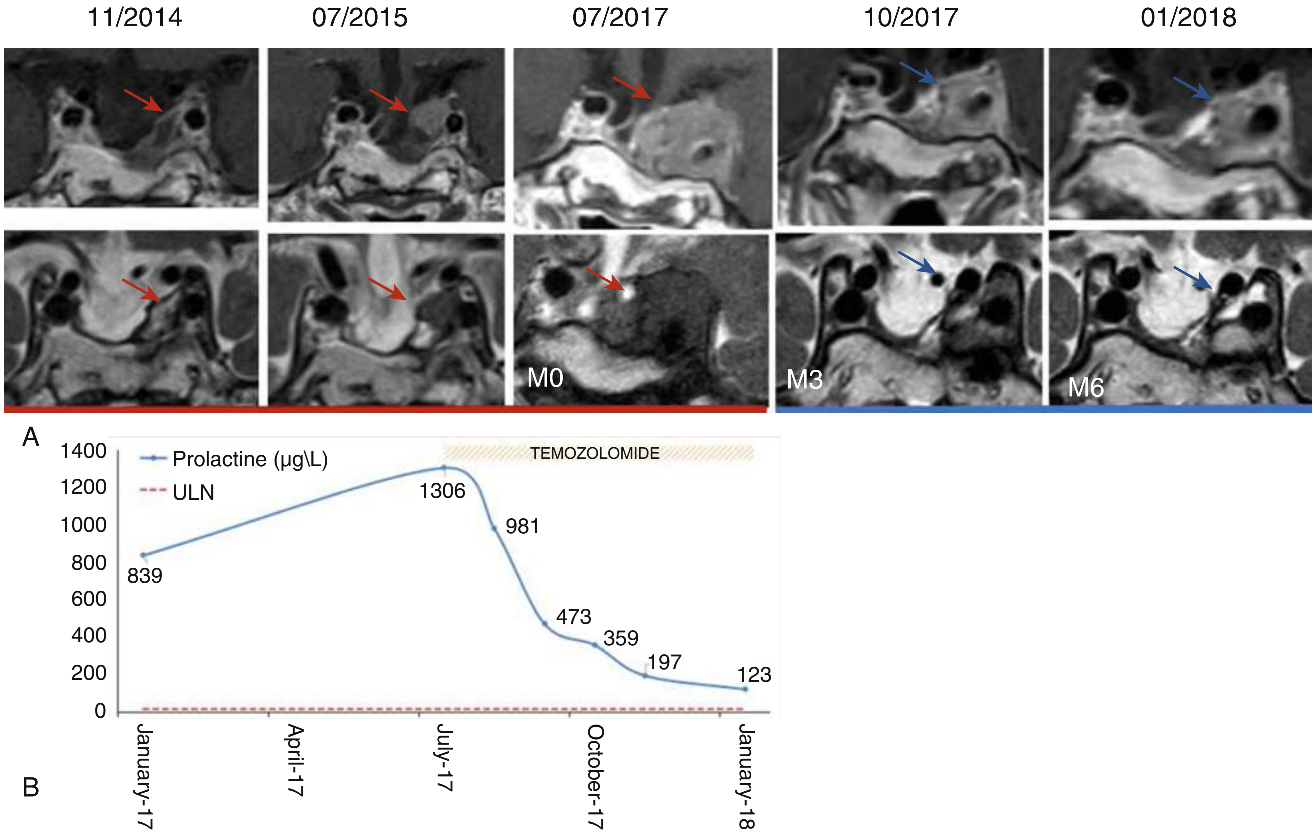

Fig. 15.4 Illustration of aggressive prolactinoma: radiological and hormonal follow-up before and after temozolomide treatment. **A,** Coronal T1 and T2 magnetic resonance imaging follow-up demonstrating tumor progression (*red arrow* indicates growing residual tumor) before temozolomide treatment (*red line*), and tumor response (*blue arrow* indicates shrinkage of the residual tumor) after 3 (M3) and 6 (M6) months of treatment (*blue line*). **B,** Graphical illustration of prolactin secretion before temozolomide and response after three and six cycles of temozolomide 200 mg/m^2 daily for 5 days every 28 days. *ULN,* Upper limit of normal.

selected patients with large residual tumors associated with clinical signs and pathology that point to a risk of aggressiveness.[63]

KEY POINTS

- Temozolomide is the first-line treatment for aggressive pituitary tumors and carcinomas. In some instances it could be considered for use as part of a Stupp protocol rather than only as salvage therapy.

Recent publications showed that a response to TMZ was associated with significant improvement in overall survival in responders compared with nonresponders (44 months vs. 16 months, respectively).[15] Progression-free survival after TMZ cessation was between 23 to 30 months,[15,61] and TMZ rechallenge in these patients was rarely efficient,[55] raising questions about the optimal duration of TMZ treatment. The ESE guidelines propose that, in responders, TMZ should be continued for 6 months or more when a continued therapeutic effect is noted[2]; however, data regarding the outcomes of long-term treatment are too limited to recommend its maintenance over time or for a specific duration. Some reports suggest that TMZ could be effective and well tolerated even after 2 years of treatment; however, to limit its potential cumulative toxicity, in our practice, we try to decrease the TMZ dose by half after 24 cycles.

KEY POINTS

- In responding patients, a longer duration of temozolomide treatment may be considered; however, despite its efficacy in about 40% of cases, there is still a need for alternative therapies. Among these alternatives, immunotherapy or antivascular endothelial growth factor should be considered.

The most frequent adverse effects are cytopenia (mostly thrombocytopenia), fatigue, nausea/vomiting, and abnormal liver function tests. A hematological profile should be obtained 7 days before starting a new cycle during standard treatment. In the presence of thrombocytopenia, a dose reduction or delay in treatment cycles can be proposed to allow continuation of the treatment.

Combination of TMZ with other therapeutic agents has also been described, including combination with capecitabine ($n = 4$) or bevacizumab ($n = 6$), but no conclusion could be drawn regarding the benefit of these combinations in light of the limited number of cases and their highly variable clinical presentation.[55,62]

Identification of markers that predict response to TMZ may assist in decision making in some circumstances. MGMT expression has been suggested as a potential predictive marker of tumor response to TMZ because MGMT-negative tumors typically exhibit a good response, and MGMT-positive tumors rarely achieve regression; however, the results have been inconsistent across a number of studies.[13,15,55,64] The inconsistency associated with these results may be caused by technical issues associated with MGMT immunostaining and the absence of an agreed cut-off to determine positive MGMT expression, but also to differences between the tumor tissue analyzed (obtained at the time of the surgery) and the same tumor at the time of TMZ treatment initiation.[15,65] MGMT methylation status has not been validated as a predictive marker of tumor response in pituitary tumors treated with TMZ.[2] Hirohata et al. studied the expression of DNA MMR proteins using immunohistochemistry and found that a lack of expression was associated with resistance to TMZ,[65] but this difference was not found in another study.[59]

Therapeutic Perspectives

Peptide Receptor Radionuclide Therapy. Peptide receptor radionuclide therapy (PRRT) is a site-directed targeted therapeutic strategy that specifically uses radiolabeled SSTR-binding molecules designed to deliver cytotoxic levels of radiation to tumor cells that express these receptors.[66] Most pituitary tumors express SSTRs, but so far PRRT has only been tested in a limited number of aggressive pituitary tumors or carcinomas. We recently reviewed the results of the 20 patients who have been treated using this approach.[62] Information regarding the initial presentation was available for 11 patients (three female and eight male patients): four nonfunctioning, two somatotroph, two lactotroph, one somatotroph-lactotroph, and two corticotroph (including one silent) tumors. None of these patients demonstrated a complete tumor response, three presented a partial response, three were stable, 11 progressed during treatment, and data were missing for three patients. These rare cases do not allow the identification of predictive markers of tumor response; however, five out of the six patients who exhibited stable disease or a partial response had not been previously treated with TMZ, suggesting that an earlier use of PRRT in potentially aggressive pituitary tumors, instead of as a salvage therapy, might work better. Potential side effects, mainly affecting bone marrow (transient anemia, thrombocytopenia, and/or leucopenia) and kidney, should be also taken into consideration.

Antivascular Endothelial Growth Factor Monoclonal Antibody. Although described in only 12 patients, bevacizumab is the alternative drug that has been most often used in the treatment of aggressive pituitary tumors and carcinomas, thus far being administered as monotherapy or in combination with TMZ. Results with this drug have shown a complete response in one corticotroph carcinoma,[67] whereas a partial response was seen in three patients, stable disease in five, and progressive disease in two.[62] These results are encouraging, but a reporting bias, with publication of only the successful cases, cannot be excluded.

Mammalian Target of Rapamycin Inhibitors. Rapidly accelerated fibrosarcoma/mitogen activated protein kinase/extracellular-signal-regulated kinase and phosphoinositide 3-kinase/protein kinase B/mammalian target of rapamycin are key signaling pathways that interact with each other to regulate cell growth and progression in pituitary tumors.[68] Everolimus, an mTOR inhibitor, has been shown to have antineoplastic activity *in vitro*, both in pituitary cell lines and in primary cultures.[69,70] Unfortunately, these encouraging preclinical results have not been confirmed by clinical experience. Of the six patients treated using this approach reported in the literature, only one, with an aggressive lactotroph tumor, presented stable disease (follow-up of 12 months).[62] The side effects with this treatment are generally mild, including fatigue, rash, stomatitis, diarrhea, myelosuppression, hyperglycemia, and hyperlipidemia.

Tyrosine Kinase Inhibitors. Following the demonstration that human prolactinomas express nuclear endothelial growth factor (EGFR), membranous EGFR, ErbB2, ErbB3, and ErbB4, and that their expression correlates with tumor invasion,[71] Cooper et al. conducted a pilot study examining the potential effect of lapatinib (a dual ErbB1/ErbB2 inhibitor) 1250 mg daily for 6 months in the treatment of aggressive prolactinomas. All six cases reported were dopamine-resistant lactotroph tumors not previously treated with TMZ. At 6 months, tumor volumes were stable ($n = 4$) or increased ($n = 2$), whereas hormone secretion demonstrated a partial response ($n = 3$) or increase ($n = 3$).[72,73] Four other cases of unknown tumor type that received lapatinib, erlotinib (an ErbB1 inhibitor), or sunitib (a multitargeted tyrosine kinase inhibitor) after TMZ showed progressive disease.[13,62] Tyrosine kinase inhibitors are associated with numerous side effects because of their actions on normal tissue. The most common adverse effects with lapatinib include diarrhea, moderate fatigue, nausea, and an acneiform rash.

Immune Checkpoint Inhibitors. Immune checkpoint inhibitors (ICIs) are monoclonal antibodies developed for the treatment of various cancers. ICIs target key points involved in immune system tolerance to tumors, including cytotoxic T lymphocyte antigen 4 (CTLA4), programmed cell death protein 1 (PD1), and its ligand, programmed cell death 1 ligand 1 (PDL1), thus enhancing the antitumor response.[74] The identification of tumor-infiltrating T lymphocytes and of PDL1 expression in pituitary tumors opened the door to this new therapeutic option for aggressive pituitary tumors and carcinomas.[75,76] Lin et al. published the first case of a corticotroph carcinoma showing a partial response on combined treatment with nivolumab (anti-PD1) and ipilimumab (anti-CTLA4).[77] Following this first publication, three other cases have since been published. Two patients were treated with a nivolumab and ipilimumab combination: one had a corticotroph carcinoma that responded to the treatment, and one had an aggressive prolactinoma that progressed during the treatment.[78] Finally, one patient with an aggressive corticotroph tumor presented rapid progression on pembrolizumab (anti-PD1).[79]

ICIs may be a good alternative for patients who show progression during or after TMZ treatment because TMZ induces somatic hypermutations, which may be associated with treatment response to immunotherapies.[77] However, the limited number of published cases does not allow any conclusions to be drawn, especially because ICIs, which were initially considered a promising option for numerous types of cancers, proved to be effective in only a minority of cases, and this efficacy may also be affected by gender.[80] Although the numbers are too limited to draw firm conclusions, the two responding patients were females, whereas the two males treated for pituitary tumors did not respond. It is noteworthy that microenvironments and genomic alterations are different among different pituitary tumor types; therefore, the tumor response to ICIs should be evaluated for each tumor type. For example, gonadotroph tumors, which present fewer tumor-infiltrating lymphocytes[81-83] and having fewer genomic alterations[47] may not be good candidates for treatment with ICIs.[84] The results from the two clinical trials on combined immunotherapy with ipilimumab and nivolumab that are currently underway (NCT04042753 and NCT02834013) may help physicians to better select patients to be treated with ICIs.

The potential downsides of therapy with ICIs are immune-related adverse events that can affect every organ, but particularly the skin (pruritus, rash, vitiligo), gastrointestinal tract (colitis, diarrhea), liver (hepatitis), and endocrine system (hypophysitis, primary adrenal insufficiency, dysthyroidism, and diabetes).[85]

CONCLUSION

The recent ESE guidelines on the management of aggressive pituitary tumors and carcinomas provided clinicians with the first signposts guiding the management of such patients. However, the definition of aggressive tumors is subject to individual interpretation, and a clearer definition of tumor growth velocity is needed. Although the majority of pituitary tumors are benign, we suggest that aggressive pituitary tumors and carcinomas should be included in cancer registries. Such a registry would allow clinical and pathological data to be amassed that can be used to improve our ability to identify tumors with a high risk of recurrence or of progression during medical treatment, and to evaluate responses to different therapeutic options. To date, TMZ is the best therapeutic option available, but whether it should be used earlier in the disease course and the optimal treatment duration remain open questions. Acknowledging that not all of these tumors are benign will help in the identification of predictive markers of aggressiveness and allow the development of both a personalized medicine approach and alternative therapies.

INTRODUCTION

Although surgery represents the standard initial approach for the treatment of pituitary adenomas and provides long-term local and hormonal control in patients with completely excised lesions, radiotherapy is effective in patients with growing residual and recurrent adenomas and in tumors not amenable to surgery or medical treatment. It provides excellent rates of tumor control (>90% at 10–20 years) and control of hormonal hypersecretion in secreting adenomas, albeit with a delay.

Advances in radiotherapy techniques allow the delivery of an effective therapeutic dose to the tumor with a substantial reduction in the amount of dose to the surrounding brain, thereby potentially limiting the risk of treatment-related long term side-effects. We provide an overview of the role, effectiveness, and side-effect profile of current and evolving techniques of irradiation in secreting and nonsecreting pituitary adenomas.

INDICATIONS FOR PITUITARY RADIOTHERAPY

The optimal management of pituitary adenomas requires collaboration between surgeons, endocrinologists, radiologists, and clinical oncologists. The indication for radiotherapy has evolved in parallel with improvements in surgical techniques and the use of high-quality magnetic resonance imaging (MRI). The decision when to use radiotherapy requires striking a balance between its benefits and risks, especially in the context of a largely benign disease.

Radiotherapy had been considered for all patients with residual lesions after surgery, but is no longer *routinely* used as adjuvant treatment. In patients with residual nonfunctioning tumors following surgery, radiotherapy is generally withheld unless there are histological features suggestive of more aggressive behavior, or until there is evidence of tumor progression or particular concern about risk to vision. In progressive nonfunctioning and secreting adenomas, radiotherapy is highly effective in achieving tumor control in over 90% of patients at 10 years, and in the region of 90% at 20 years.[1-9]

In patients with functioning tumors, radiotherapy is considered where hormonal normalization is not achieved with surgery and/or medical therapy and in rapidly progressive or recurrent lesions. Hormone levels decline at a constant rate, with normalization reached over months or years after treatment, depending on pretreatment hormone values.[10,11]

KEY POINTS

- Radiotherapy is a recognised treatment option for non-secreting and secreting pituitary adenomas with residual progressive tumors after surgery, providing high rates of local tumor control and hormonal normalisation.

RADIOTHERAPY TECHNIQUES AND FRACTIONATION

Regardless of the technology adopted, the principles of pituitary radiotherapy are to:

- Accurately identify the treatment target within the sella and surrounding region,

- Accurately identify critical adjacent normal structures,
- Precisely deliver a predefined dose of radiation to the target, and
- Minimize the dose received by the surrounding neural structures to minimize the risk of normal tissue injury.

Modern radiotherapy integrates precise patient immobilization and high-quality imaging in the initial treatment preparation (planning) and during treatment. The absence of randomized controlled trials does not allow a direct comparison of different radiotherapy procedures and delivery techniques in terms of clinical outcome, and the advantages and disadvantages of the available technologies and their optimal indications remain a matter of debate.

KEY POINTS

- Radiotherapy techniques have evolved over time allowing better dose-conformality to the target, with less radiation reaching neighboring normal tissues. The standard of care remains highly-conformal fractionated radiotherapy with daily treatment over 4-5 weeks, while small pituitary lesions away from the optic apparatus may be amenable to single fraction radiosurgery.

Three-Dimensional Conformal Radiotherapy

Three-dimensional conformal radiotherapy (3D-CRT) given in multiple daily fractions (fractionated 3D-CRT) is the standard of care for pituitary radiotherapy. The treatment is given with photons (high-energy x-rays) using a linear accelerator (linac) and can be used to treat lesions of any size.

The patient is immobilized, either in a fixed or relocatable frame system, or more commonly in an individually molded relocatable plastic mask. The relocation accuracy of the immobilization mask is operator-dependent and is in the region of 3 to 5 mm,[12] and can be improved to 2 to 3 mm by using a tighter-fitting mask.[13]

The extent of the adenoma and the surrounding critical structures (optic nerves and chiasm) are identified on high-resolution MRI (thin-slice T1 MRI sequences with contrast), and these are accurately coregistered with computed tomography (CT) imaging acquired for radiotherapy planning.

The visible tumor is contoured on the MRI sequences in three planes to generate a volume encompassing the macroscopic extension of the pituitary lesion. A margin that accounts for any uncertainty in volume delineation and any estimated setup variation specific to the radiotherapy center is added to generate the treatment volume.

Radiotherapy beams are shaped to conform to the shape of the target with the use of a multileaf collimator (MLC), which is an array of computer-controlled parallel leaves that creates an adjustable aperture through which the beam of radiation is delivered. In modern MLC systems the leaf width is 5 mm or 3 mm (described as mini or micro MLCs, respectively).

MLCs also allow modulation of the intensity of the radiation beam across the target; this technique is described as intensity-modulated radiotherapy (IMRT). The technique of arcing IMRT (volumetric-modulated arc therapy [VMAT] or *RapidArc*) allows delivery of the radiation dose continuously while the linac rotates around the patient and offers a fast way of delivering complex, highly conformal treatments. VMAT/*RapidArc* is the currently preferred technique for high-precision treatment delivery.

The total dose prescribed in pituitary adenomas using 3D-CRT is 45 to 50 Gy given in daily fractions of 1.8 to 2 Gy 5 days per week. This dose is below the radiation tolerance of the surrounding critical neural structures, so additional dose constraints and specific avoidance of the adjacent organs are not generally employed. With increasing understanding of the sensitivity of functional structures, such as the hypothalamus and subregions of the temporal lobe, more refined avoidance of sensitive structures can be employed in the future. Most studies suggest that a dose of 45 Gy is sufficient for benign pituitary adenomas. See Fig. 16.1 for a radiotherapy plan using RapidArc.

Stereotactic Radiotherapy Techniques

Stereotactic radiotherapy (SRT) is a refinement of 3D-CRT in which the combination of more robust patient immobilization with accurate target identification provides a more precise method of treatment delivery that allows for a tighter margin around the treatment volume, and hence a reduction in the volume of normal brain tissue irradiated to high doses.[14] The principal aim of normal tissue sparing is to reduce the long-term toxicity of radiotherapy while maintaining its effectiveness.

Originally, the term "stereotactic" referred to the use of three-dimensional (3D) coordinates defined by external markers in relation to a neurosurgical type frame fixed to the head. While used in neurosurgical practice to define the site of a biopsy using the 3D x, y, and z coordinates, it was adopted in radiotherapy to determine the location of a lesion to be treated. For the purposes of high-precision radiotherapy, the traditional stereotactic localization has been superseded by the integration of modern imaging (CT and MRI) with less invasive forms of head immobilization, but the term "stereotactic" remains as a way of describing a precise method to deliver localized radiotherapy. As currently practiced, stereotactic radiotherapy should be appropriately termed "high-precision conformal radiotherapy."

All radiotherapy technologies use sophisticated on-treatment imaging systems (described as image guidance techniques) to ensure the treatment is delivered correctly. These include on-treatment CT imaging (cone beam CT), in-room x-ray imaging, and, more recently, MRI, and these are coupled with sophisticated automatic correction algorithms integrated with patient positioning devices with automatic adjustments to correct for potential errors.

Stereotactic, or high-precision, radiotherapy can be given using a number of radiotherapy delivery systems, which include a modern linac, multiheaded cobalt unit (Gamma Knife [GK]) and a small linac-mounted on a robotic arm coupled with an image-guided system (CyberKnife [CK]).

Linear Accelerator. Linacs are the "standard" radiotherapy machines used to deliver most radiotherapy treatments. Modern linacs fitted with image guidance systems are routinely used without specific modifications to perform SRT/high-precision conformal radiotherapy. The rotating, isocentrically-mounted linac allows for almost full spherical access to the target, resulting in homogeneous treatment dose delivery.

Gamma Knife. The GK, developed in the late 1960s, consists of multiple cobalt-60 sources arranged in a hemispherical distribution. The generated multiple beams of gamma radiation converge through a system of collimation at a single point (isocenter) to obtain a circumscribed spherical dose distribution within the treatment target. In the current version of the device, the cobalt sources are arranged in concentric rings, each one of which is able to move in a linear direction over an internal collimator, with several stopping positions. Each position corresponds to a different collimator size (from 4 to 16 mm) to produce beams of radiation of different spherical diameters or to selectively block specific groups of beams. The combination of several spherical doses of radiation allows the coverage of larger targets or nonspherical targets with a multiple isocentric arrangement.[15]

CyberKnife. Miniaturized linacs mounted on a robotic arm, commercially known as the CK, deliver many small photon beams under continual x-ray image guidance. The robotic arm has 6 degrees of freedom of movement, with a limited cone of access to create a dose distribution tightly conforming to the treatment target. The latest version of

C, Axial planning computed tomography (CT) showing conformality of high-dose radiation region (displayed as *color wash*) to the target *(cyan contour)*, to ensure coverage of the target treatment volume by at least 95% of the prescribed dose and minimal dose outside target. D, Axial planning CT showing the dose distributions of higher and lower isodoses, demonstrating the dose fall-off outside the target. Dose falls off concentrically with distance from the high-dose target area.

the system is equipped with a multileaf MLC to shape the radiation beam and alter its intensity. The miniaturization results in small, low-output beams that require long treatment times.

Radiotherapy Fractionation

SRT can be delivered as fractionated treatment (fractionated stereotactic radiotherapy [FSRT]) delivering a treatment course over days or weeks, where the prescribed dose is given usually in small daily doses (fractions), or as a single high-dose treatment (described as stereotactic radiosurgery [SRS]).

The choice of radiotherapy fractionation is based in part on the size and location of the pituitary adenoma and the constraints demanded by the technology used. In the absence of randomized trials, the choice should be based on evidence of long-term outcomes of large cohorts of patients with data on long-term actuarial tumor and hormonal control, as well as the toxicity risks.

Most pituitary adenomas requiring radiotherapy lie in proximity to the optic apparatus and the nerves of the cavernous sinus. As the risk of radiation-induced optic neuropathy is dose- and fractionation-dependent, it is mandatory to spare the optic apparatus beyond single doses of 8 to 10 Gy to avoid unacceptable toxicity.[16,17] SRS is therefore reserved for small adenomas (≤3 cm) away from the optic apparatus (usually ≥3–5 mm distance between the target and the optic apparatus).

The rationale of dose fractionation is to lessen the risk of injury of the normal tissue surrounding the radiotherapy target, and therefore the risk of developing radiotherapy-related side effects. The total dose prescribed with FSRT for pituitary adenomas is 45 to 50 Gy delivered in fractions of 1.8 to 2 Gy. This dose range is below the tolerance of the central nervous system neural tissue, with a less than 1% to 2% risk of radiation-induced damage to normal cranial nerves.[16]

The use of a high single-dose of radiation, other than undoubted convenience, assumes that large doses per fraction may produce greater antitumor efficacy than predicted by classical radiobiological models for conventional fractionation.[18,19] The validity of these models at high doses per fraction is controversial, and they are not validated for single-fraction treatments or in the context of benign tumors. Currently, the available outcome data do *not* show superiority of SRS over fractionated irradiation in the treatment of pituitary adenomas.

Linear Accelerator–Based Fractionated Stereotactic Radiotherapy

FSRT is used to treat adenomas of all sizes, including lesions abutting or displacing the optic apparatus. Patients are immobilized in relocatable frames or in precisely fitting thermoplastic mask systems. On-treatment imaging carried out immediately before treatment (orthogonal x-rays or cone beam CT scans) enables instant, real-time correction for patient positioning deviations to ensure the precision of the daily treatment, which is generally of submillimeter accuracy.[20]

The treatment volume is irradiated with multiple fixed fields or, more frequently, with arcs (VMAT/*RapidArc*) at each daily session.

Linear Accelerator–Based Stereotactic Radiosurgery

Linac-based SRS can be used to treat adenomas less than or equal to 3 cm in maximum diameter. For larger lesions, treatment can be given in a few fractions, described as hypofractionated treatment ("hypofractionated SRT").

Gamma Knife Stereotactic Radiosurgery

Single-fraction GK treatment is used for small lesions not exceeding 3 cm in maximum diameter that are more than 3 to 5 mm from sensitive, critical structures.

Traditionally, the immobilization is with a fixed head frame attached to the outer layer of the skull under local anesthetic at four fixation points. The planning process (frame fixation and treatment planning scan) and the radiosurgical procedure are carried out on the same day.

Multiple isocenters are generally required to conform the treatment dose to the irregular shape of targets such as pituitary adenomas. This approach generates areas of inhomogeneous dose distribution within the target, where the contribution of different overlapping spheres of radiation can produce "hot spots" (areas of high doses of radiation).

Modern GK units can use frameless thermoplastic masks for immobilization to perform hypofractionated SRT, particularly for larger lesions. The system is equipped with a cone-beam CT for image guidance and a motion tracking device for monitoring the patient's position during treatment.

CyberKnife Stereotactic Radiosurgery

Patients are immobilized in closely fitting thermoplastic masks, and treatment for pituitary adenomas can be delivered as a single fraction or, more commonly, with a hypofractionated SRT regimen over two to five fractions. During treatment, the head position is monitored with real-time x-ray imaging, and the position of the beam in relation to the target is adjusted in real time.

Proton Therapy

Proton beam therapy (PBT) exploits the physical properties of heavy charged particles with dose deposition at depth over a narrow range (the so-called Bragg peak). Modern PBT is associated with some dose reduction beyond the target that can be theoretically associated with a better side-effect profile.[21] It is currently used as fractionated conformal radiotherapy for selected brain tumors, including pituitary adenomas, although the evidence of benefit remains unproven. Immobilization devices are similar to those used for photon-based techniques, and newer proton machines are equipped with cone-beam CT for image-guidance.

CLINICAL OUTCOMES OF PITUITARY RADIOTHERAPY

The management of pituitary tumors has changed considerably over the years. Although surgery remains the primary treatment for nonfunctioning pituitary adenomas (NFPA) and GH- and ACTH-secreting tumors, surveillance and medical treatment play a greater role pre- and postoperatively, and radiation is used less frequently.

The principal focus of the majority of the publications has been on relatively easily measurable endpoints of tumor control and hormonal control. When considering the efficacy of treatment for benign conditions, the outcome should be of clinical relevance to the patient. In pituitary radiotherapy, while tumor control remains of importance, endpoints such as preservation of vision, symptoms from excess/deficient hormone secretion, quality of life, and overall survival (which may not always be related to tumor control) are of principal clinical relevance.

Evidence for Fractionated Radiotherapy and Changes in Practice Over the Years

Reported recurrence rates after transphenoidal surgery alone for NFPA vary between 15% and 66%,[22,23] likely reflecting variations in patient population, surgical technique, and expertise, as well as in tumor biology.

Historically, postoperative radiotherapy was offered routinely to reduce the risk of tumor recurrence/progression. Nonrandomized studies suggested lower rates of tumor recurrence in patients treated with adjuvant radiotherapy; a summary of studies comparing the outcomes after adjuvant fractionated radiotherapy with no radiotherapy is shown in Table 16.1.[1,23-31]

However, the likelihood of recurrence is low following apparent complete excision, with recurrence risk largely confined to patients with subtotal excision.[27,32] The combination of excellent results following complete excision, the lack of randomized trials comparing adjuvant radiotherapy with surveillance, improvements in surgical techniques, and imaging and concern about potential late effects of radiotherapy have led to replacement of adjuvant radiotherapy with a policy of surveillance. Radiotherapy is currently reserved for patients with unresectable and progressive residual or recurrent tumors considered a threat to vision, or if the histology demonstrates atypical features suggesting a less benign tumor variant.

The recommended radiation doses for fractionated treatment, despite changes in delivery techniques, have remained largely unchanged, which is reasonable in the context of excellent long-term tumor control. The higher accuracy of dose delivery and better

avoidance of adjacent normal tissue of stereotactic/high-precision techniques associated with lower doses to normal structures are assumed to translate into clinical benefit.

Development of Radiosurgery

The comparison of outcomes of single-fraction SRS with fractionated FSRT currently relies on comparisons of retrospective studies with inevitable selection bias, particularly based on tumor size and proximity to critical structures.

The recommended SRS dose for NFPAs is 12 Gy peripheral dose as the minimum effective dose, with no benefit to doses greater than 20 Gy,although some authors recommend a higher dose of 14 to 16 Gy.[33] There is no clear evidence whether dose escalation is beneficial for tumors with aggressive or atypical features. Higher doses are frequently used for functioning tumors, with doses of 15 to 3 5Gy (stereotactic-radiosurgery-radiotherapy-evidence-review.pdf) (england.nhs.uk), although this is not evidence based.

Fractionated radiosurgery schedules (hypofractionated SRT) with doses of 12 to 25 Gy delivered in three to five fractions are associated with good short-term outcomes, but here too longer-term follow-up data are required.[33]

KEY POINTS

- Outcome data for radiotherapy treatment of pituitary adenomas are largely derived from retrospective studies without prospective randomised trials comparing treatment techniques.

EFFICACY OF RADIOTHERAPY

Overall Survival

Overall survival is generally considered the most important clinical outcome in oncological studies, and its assessment includes excess mortality because of the disease and because of the treatment. While of relevance in patients with benign tumors such as pituitary adenomas, patients generally live for decades, and therefore the overall study time makes reliable survival outcome data collection less achievable, and results take decades to obtain. Overall survival, while a desirable outcome measure, is currently not an available endpoint for the assessment of NFPA outcomes.

Radiological Tumor Control: Progression-Free Survival

MRI tumor control, defined as progression-free survival (PFS), is a pragmatic objective endpoint allowing for comparison of treatment efficacy across studies. Although recurrence of a benign pituitary tumor is unlikely to directly affect survival, it is associated with increased morbidity and is therefore a useful outcome for assessment of treatment efficacy.

Fractionated Treatment (Three-Dimensional Conformal Radiotherapy and Fractionated Stereotactic Radiotherapy).

Studies assessing the outcome of fractionated radiotherapy demonstrate excellent tumor control, with total doses usually between 45 and 50.4 Gy delivered at 1.8 to 2 Gy per fraction, and are summarized in Table 16.2. The reported 10-year PFS rates for CRT and 3D-CRT are 86% to 100%, and appear to be maintained around 90% at 20 years.[1-5,7,8,34-48] Some patients treated in the era of conventional and conformal techniques will have received adjuvant radiotherapy regardless of the extent of surgical excision, and therefore these outcomes may represent a population with an overall lower risk of recurrence. After FSRT, even when mostly carried out for residual/recurrent tumors, the reported 5-year PFS is in the region of 95% to 99%, 10-year PFS is reported at 90%, and 20-year PFS is reported at 88%.[34,36,42,49-54]

The reported tumor control rates for NFPA treated with SRS are 95% to 97% at 5 years and 85% to 87% at 10 years,[55] when a marginal dose of 18 Gy is delivered.[56] These data are summarized in Table 16.3.[55-60] This is considered by some to be inferior compared with the results from fractionated treatment, as SRS is reserved for patients with smaller tumors, and the 10-year control rates appear similar to the 20-year rates reported after FSRT/3D-CRT.

Although systematic reviews and metaanalyses reported pooled outcome data from retrospective studies,[33,61] the heterogeneity of the studies, the variability in outcome reporting, and the short follow-up do not allow for reliable conclusions about comparative efficacy.

Hormone Normalization

For functioning pituitary tumors, normalization of hormone levels is an appropriate outcome, although this may also be considered a surrogate endpoint. The time taken to achieve hormone normalization varies with pretreatment levels. Time to normalization should be reported

together with the rate of hormone decline as the time to halving of pretreatment hormone levels to allow comparisons of treatment efficacy. The assessment of hormone level response is also complicated by the use of medical therapies, making it difficult to disentangle the effects of radiotherapy and medical treatment.

For patients with acromegaly, radiotherapy is usually reserved for those who failed surgical and medical therapy, although with improvements in radiotherapy delivery techniques, it may be recommended in selected patients as second-line treatment after surgery.[62,63] For ACTH-producing tumors, in the reported studies there is considerable heterogeneity in the measurement and definition of biochemical remission (as defined by serum cortisol and 24-hour urinary free cortisol) and a lack of consensus as to how best to define "normalization." Radiotherapy is recommended for patients with persistently raised cortisol levels after surgery, or those with known unresectable residual disease. For prolactinomas managed with medical therapy and, failing that, surgery, radiotherapy tends to be third-line treatment. Outcomes from radiotherapy for prolactinomas are therefore reported for heavily pretreated tumors resistant to other therapies.

Fractionated Treatment (Three-Dimensional Conformal Radiotherapy and Fractionated Stereotactic Radiotherapy). For functioning tumors, normalization of hormonal levels is achieved in the majority of patients, although it can take months to years, and the rate and time taken to normalization vary with the hormone axis and the pretreatment levels. Publications reporting hormonal responses after 3D-CRT and FSRT are summarized in Table 16.4.[5,10,38-40,46,48,64-71]

In patients with GH-secreting tumors, the median time to halving of GH level is in the region of 2 years after CRT. The time to normalization of GH/IGF-1 levels related to the pretreatment GH level[40,64,72] varies widely between studies; following FSRT, GH normalization was reported in 84% of patients after a median follow-up of 26 months in one study, but in only 33% to 35% of patients at 39 months in two other studies,[50,65] and normalization can take up to 10 to 15 years.

In patients with ACTH-secreting adenomas, fractionated radiotherapy results in biochemical remission in 42% to 83% of patients,[72,73] with a median time to remission of 18 months. A 50% reduction in urinary free cortisol has been measured at 6 to 12 months after treatment, and in serum cortisol at approximately 1 year. Normalization of cortisol levels has been reported in 73%, 78%, and 84% of patients at 3, 5, and 10 years, respectively, after fractionated radiotherapy.[74] Similar outcomes are reported after FSRT, with tumor control rates of 99% at 5 years, and the results for ACTH response are likely to be similar to those achieved with CRT.[75]

Surgery is the primary treatment for gonadotroph pituitary tumors. Radiation treatment tends to be reserved for refractory tumors, although long-term outcomes are not clear.[75]

Despite being reserved for heavily-pretreated prolactinomas, radiotherapy has been reported to achieve 90% tumor control at 10 years and up to 20% to 60% hormone control.[72,76] In patients with prolactinomas treated with FSRT, at a median follow-up of 43 months (median 6–60 months), 33% of patients had normalization of serum PRL levels with reported times to normalization ranging from 5 to 40 months.

TSH-secreting adenomas are extremely rare and are usually controlled by surgery, with variable biochemical remission rates ranging from 35% to 84%.[75] Radiation therapy may be used in patients who do not achieve biochemical remission after surgery.

Radiosurgery (Stereotactic Radiosurgery and Hypofractionated Stereotactic Radiosurgery). Endocrine outcomes following radiosurgery are mostly reported as hormone "normalization" affected by pretreatment hormone levels, which are likely to be lower for the

smaller tumors amenable to SRS.[77] In the absence of reporting the rate of hormone decline, comparison to other treatment techniques is difficult, if not impossible.

For GH-secreting tumors, a metaanalysis has shown that, at 5 years, estimated endocrine remission and endocrine control rates were 43.2% and 55.0%, respectively. At 10 years, these rose to 56.9% and 69.7%, respectively, and the estimated 10-year local control rate was 92.8%.[78] Better chances of remission have been reported in patients with lower pre-SRS IGF-1 levels.

For ACTH-producing tumors, approximately 50% of patients had biochemical remission at a corrected median follow-up of 42 months after SRS.[79] The time to hormonal response ranged from 3 months to 3 years, with no clear difference in the rate of hormonal decline compared with fractionated radiotherapy. Radiologic control was reported in up to 98% at a median follow-up of 4 years.[80] In other studies, biochemical remission was reported in 54% to 70% of patients at 5 to 10 years[80,81] and a median time to remission of 16.6 months, similar to fractionated treatment (18 months).[75] Although SRS for Cushing disease achieves high initial remission rates, approximately 20% of patients subsequently relapse.[82] [83] Comparisons between studies should be made with caution, as inevitably the treated populations will have wide variations in initial hormonal levels.

In prolactinomas, biochemical remission after SRS has been reported in 14% to 26% of patients who did not respond to medical or surgical approaches.[75,84,85] Remission is more likely to be achieved in patients with smaller adenomas and those that do not require dopamine agonist therapy at the time of radiotherapy.[84]

Visual Function

Visual function is one of the most relevant clinical outcomes for evaluation of treatment efficacy, particularly in patients with NFPA, and changes can be usefully assessed over a shorter time frame than that required for survival assessment. Effects of treatment can be measured objectively as improvement in visual fields and acuity following treatment. As radiotherapy is associated with a small risk of visual deterioration, the risk needs to be factored in when evaluating treatment outcome (see Toxicity section later).

Fractionated Treatment (Three-Dimensional Conformal Radiotherapy and Fractionated Stereotactic Radiotherapy). Improvement in vision has been noted after surgery alone, and progressive improvement in visual acuity may continue for a year after treatment.[86] Improvements in visual impairment have also been reported in many studies of fractionated radiotherapy, with up to 55% to 78% experiencing improvement[4,87] after postoperative fractionated radiotherapy. In a separate study, following FSRT vision was stable in those with normal vision preradiotherapy and improved in 36% of those with visual impairment.[52]

Radiosurgery (Stereotactic Radiosurgery and Hypofractionated Stereotactic Radiosurgery). There are limited data on improvements in visual function following SRS, most likely because of the contraindication to SRS of tumors close to the optic apparatus. However, improvement in visual function has been noted even for tumors close (<3 mm) to the optic apparatus.[88]

KEY POINTS

- Fractionated high-precision radiotherapy results in high rates of local control at 10 and 20 years (in the region of 90-95%), while the rate of hormone decline is specific for each hormone axis; normalisation occurs with a delay principally related to pre-treatment hormone levels.

TOXICITY OF RADIOTHERAPY

Acute side effects occur within 3 months of treatment, and long-term effects develop months or years after radiotherapy. Acute side effects include tiredness, temporary hair loss at the irradiation site, and minor skin reactions. They are transient and resolve within a few weeks, and none lead to long-term sequelae.

Radiotherapy to a pituitary adenoma leads to some inevitable irradiation of surrounding normal structures, which include cranial nerves, blood vessels, surrounding normal brain including the hypothalamus, and residual normal pituitary. Long-term side effects therefore include some risk to all these structures, although with conventional radiotherapy the dose delivered is below the radiation tolerance, and therefore the risk of damage is low, although it may be expressed late.

KEY POINTS

- The risk of radiation induced long-term toxicity following fractionated radiotherapy is low with hypopituitarism the most common side effect, while vascular toxicity and visual impairment are rare sequelae. Radiosurgery data is less mature with no clear difference between the toxicity outcomes for small tumors compared to conventionally-fractionated treatment.

Hypopituitarism

Radiation-induced hypopituitarism is a consequence of functional radiation damage to the hypothalamus and the pituitary, and the risk is affected by damage to the hypothalamo-pituitary axis from the direct effect of the tumor and from surgery. Because of the adverse impact of untreated hypopituitarism on survival,[89] patients treated with radiotherapy require long-term monitoring and hormone replacement.

Fractionated Treatment (Three-Dimensional Conformal Radiotherapy and Fractionated Stereotactic Radiotherapy). After fractionated conformal radiotherapy, the risk of hypopituitarism is in the region of 30% at 5 years and 50% at 10 years.[4,5,38,40,43,44,90-92] The risk of radiation-induced hypopituitarism is dose-dependent, and it occurs more commonly after total doses of greater than 45 Gy or fraction size greater than 1.8 to 2 Gy for fractionated treatment. Higher rates of radiation-induced hypopituitarism have been reported in patients with functioning adenomas and may be related to the frequent use of higher radiation doses (50.4–54 Gy rather than 45 Gy).[40,75]

With increasing treatment accuracy and precision, and a reduction of planning margins, the risk of radiation-induced hypopituitarism after fractioned stereotactic treatment may be reduced, but longer-term outcome data are required because current reports are of short follow-up.

Radiosurgery (Stereotactic Radiosurgery and Hypofractionated Stereotactic Radiosurgery). Early estimates of new hypopituitarism after SRS suggest a 5-year incidence of approximately 10% to 33% (see Table 16.3); assessment of the true long-term incidence requires longer follow-up combined with detailed reporting of hormonal status. As with fractionated radiotherapy, the risk of hypopituitarism after SRS is likely to be dose-dependent, with suggestion of improved outcomes with mean doses to the normal pituitary of less than 15 Gy,[93] or even less than 11 Gy.[94]

Many of the endocrine outcome data do not provide actuarial data, with no information on the length of follow-up available to be able to compare fractionated and single-fraction treatment, and claims of lower risk of hypopituitarism with SRS are currently not supported by the published data.

Visual Pathway Damage and other Cranial Nerve Injuries

Fractionated Treatment (Three-Dimensional Conformal Radiotherapy and Fractionated Stereotactic Radiotherapy). Although the doses usually used for fractionated radiotherapy (45–50 Gy) are within the tolerance of the optic apparatus, late visual toxicity is reported in 0% to 2% of patients (see Table 16.2), with most studies reporting rates of less than 2%. Longstanding compressive effects on the optic apparatus by the primary tumor may contribute to the risk. The general perception is that the likelihood of developing visual impairment as a result of radiation damage is low in patients with normal vision before starting radiotherapy, and the risk is likely to be principally in patients with already compromised vision from compression of the optic nerve and/or chiasm before treatment. The risk is also considered higher in patients with a vasculopathy, such as that associated with diabetes, although hard data on this are not available.

Reported rates of other cranial neuropathies after fractionated radiotherapy are similarly less than 1% to 2%.

Radiosurgery (Stereotactic Radiosurgery and Hypofractionated Stereotactic Radiosurgery). SRS is currently only offered to patients whose tumors are of adequate distance from the optic apparatus, and therefore the visual toxicity would be expected be lower than for fractionated treatment, where the tumor may abut the optic apparatus, which may already be compromised by prolonged compression.

The risk of optic neuropathy after SRS has been reported to affect less than 3% to 4% of patients (see Table 16.3). Although visual deterioration has been reported with doses less than 8 Gy,[59] the risk is thought to be low if the maximum point dose to the optic apparatus is below 8 to 10 Gy,[16,72,95] with significantly higher risks associated with doses greater than 12 Gy.[16,96,97] For fractionated SRS, suggested doses with limited risk of damage to the optic apparatus include less than 20 Gy in three fractions and less than 25 Gy in five fractions.[98] Other cranial neuropathies involving cranial nerve III and cranial nerves IV, V, and VI have also been also reported, with a risk of 0% to 3%[33] likely to be related to the extent of tumor infiltration and involvement of the cavernous sinus, and therefore potential preexisting damage. The rate of cranial neuropathy after SRS for Cushing disease was reported at 5%, probably a reflection of a higher dose of radiation.[80]

Radionecrosis

Fractionated Treatment (Three-Dimensional Conformal Radiotherapy and Fractionated Stereotactic Radiotherapy). Radionecrosis is reported to occur in 0.2% to 3% of patients treated with fractionated conventional radiotherapy.[72,99,100] There is no additional concern of radionecrosis with fractionated SRT, as the doses used are within the tolerance of the brain, and the risk of this is likely to be as low as or lower than with conventional or 3D-CRT (<1%).[72]

Radiosurgery (Stereotactic Radiosurgery and Hypofractionated Stereotactic Radiosurgery). The rates of radionecrosis after SRS may be higher than after fractionated treatment, with reported rates varying from 0% to 5% after SRS or hypofractionated radiotherapy.[72,101,102] Early use of SRS was associated with a high risk of radiation necrosis leading to significant concerns, but with increased understanding and greater expertise of SRS, particularly the move to restrict SRS to small lesions, the risks are reported to be low, although long-term outcomes from more recent SRS treatments need to be reevaluated.

Cerebrovascular Disease

The increased risk of stroke following pituitary radiotherapy is documented for NFPAs and functioning tumours.[89,103-106] However, the relative contribution by the radiotherapy to the excess risk is uncertain, as a number of factors are thought to contribute to the development of cerebrovascular disease. These include the pituitary tumor itself, which is associated with increased mortality mainly because of vascular disease, the cardiovascular effects of pituitary dysfunction (hormonal excess or deficiency), and the consequences of surgery.[107]

Fractionated treatment (Three-Dimensional Conformal Radiotherapy and Fractionated Stereotactic Radiotherapy). In a long-term follow-up study, the reported actuarial incidence of a stroke was 4% at 5 years, 11% at 10 years, and 21% at 20 years after radiotherapy, with a relative risk of 4.1 compared with the general population.[103,104] It has been suggested that the risk may be related to the dose delivered.[95]

It is unlikely that the increased risk is solely because of radiotherapy. Reviews of large cohorts suggest that the pretreatment duration of hypopituitary symptoms (indicative of hormone deficiency) may be a significant risk factor for stroke after pituitary adenoma treatment,[105] and both pituitary surgery and the tumor itself are likely to be contributory risk factors.[108]

The precise contribution of radiotherapy to the risk of cerebrovascular risk remains uncertain, and there are currently no clear modifiable avoidance strategies in the treatment of pituitary adenoma to reduce the risk. As patients with a history of a pituitary tumor are at higher risk of cerebrovascular disease, appropriate advice should be given for long-term monitoring and treatment of other cerebrovascular risk factors, such as hypertension, diabetes, and hypercholesterolaemia.

Radiosurgery (Stereotactic Radiosurgery and Hypofractionated Stereotactic Radiosurgery). There is a paucity of data on the risk of cerebrovascular disease after SRS. Only two studies reported cerebrovascular outcomes after SRS, and no cases were reported in small cohorts of patients.[109,110] Longer follow-up of large cohorts is required to assess the risk of cerebrovascular events after SRS.

Second Brain Tumors

Fractionated Treatment (Three-Dimensional Conformal Radiotherapy and Fractionated Stereotactic Radiotherapy). Reports of radiation-induced brain tumors following pituitary radiotherapy vary, ranging from no increased risk after radiotherapy[95,111-113] to a risk of 3% at 10 to 20 years.[43,113-118] Reported second brain tumors include meningiomas, sarcomas, neuroepithelial tumors, and gliomas.[111,112,119] How this incidence compares to a matched (unirradiated) control group of similar patients is difficult to ascertain.

In one of the largest series, the cumulative risk of second brain tumors was 2% at 10 years and 2.4% at 20 years. The relative risk of second brain tumors compared with the incidence in the normal population was 10.5 (95% confidence interval 4.3–16.7), and the relative risk was 24.3 for meningeal tumours.[115] In a further cohort, the 10-year and 20-year incidence of a second brain tumor was increased by 1.3%.[120]

Conversely, in a comparative study of over 462 patients, 236 of whom received postoperative radiotherapy, there was no significant difference in the incidence of posttreatment secondary tumors or mortality, even though the median follow-up was 14 years in those treated with radiotherapy compared with only 6 years in those treated with surgery alone.[113]

A comprehensive review of radiation-induced tumors after pituitary radiotherapy demonstrated that gliomas and sarcomas may arise from 5 years after radiotherapy and continue to rise at a constant rate until 20 to 25 years after treatment. Meningiomas have a longer latency and arise 7 to 10 years after radiotherapy,[117] and can continue to arise decades after treatment. The risk ratio in younger patients undergoing pituitary/sellar radiotherapy was reported as 3.34 for malignant brain tumors and 4.06 for meningiomas.[116]

Although there is compelling evidence for an increased incidence of tumors, it is likely that there are other contributing factors, such as the oncogenic effect of excess GH/IGF-1 in acromegaly and the immunocompromise associated with cortisol in patients with Cushing disease.[121,122]

The risk of developing a radiation-induced malignant brain tumor increased by 2.4-fold ($P = .005$) and meningioma by 1.6-fold with every 10 years of younger age at the time of radiotherapy ($P = .05$), with similar rates in patients treated with conventional radiotherapy or stereotactic radiotherapy.[116]

Radiosurgery (Stereotactic Radiosurgery and Hypofractionated Stereotactic Radiosurgery). Secondary brain tumors have not been observed after SRS in published studies, although, as a late effect of treatment, this may be because of insufficient long-term follow-up data after SRS.[72,123] However, in a large, retrospective, multicenter cohort study of nearly 5000 patients who had undergone SRS for a variety of benign brain tumors, with a median follow-up of 8 years (and minimum of 5 years), there was no increased risk of secondary malignant central nervous system tumor compared with the general population.[124]

Although the risk of second brain tumors appears to be lower after SRS than following fractionated radiotherapy,[33] longer follow-up data are required. To date, the evidence is encouraging that SRS is not associated with a significantly increased risk.

Mortality

Fractionated Treatment (Three-Dimensional Conformal Radiotherapy and Fractionated Stereotactic Radiotherapy). Although treatment is aimed at prolonging life expectancy, the beneficial effect of treatment on survival is difficult to assess for patients with benign tumors, because of the need for long follow-up of large cohorts. It is therefore difficult, if not impossible, to assess the potential effects of radiotherapy on survival, whether improvement because of tumor control or detriment because of radiotherapy toxicity.

Increased mortality has been reported in patients with NFPAs and with acromegaly treated with conformal radiotherapy, with a relative risk of 1.6 to 4.1.[72,107,125,126] Excess mortality is attributed to cardiovascular disease, and a number of factors may contribute to this, such as hypopituitarism,[33,89] the effect of excess hormone production, and previous pituitary surgery, with uncertainty regarding the contribution from radiotherapy.[72,127-130]

Radiosurgery (Stereotactic Radiosurgery and Hypofractionated Stereotactic Radiosurgery). Based on the currently available information, there is no clear effect of SRS on life expectancy, although patient selection, the absence of randomized controlled trials, and limited follow-up of SRS cohorts mean that no definite information about a potential benefit or detriment is currently available. Similarly, it is not possible to assess the relative risk of SRS versus fractionated treatment.

KEY POINTS

- Retreatment of recurrent pituitary adenoma is feasible, but should be undertaken with caution and careful counseling in view of the increased risk of toxicity.

Proton Therapy

Early reports from very small series suggest that proton treatment results in reasonable pituitary tumor control rates.[131] However, the use of proton therapy for pituitary tumors has, to date, not demonstrated any superiority over fractionated or radiosurgical techniques. Outcomes from 30 patients treated with acromegaly included an 80% decrease in GH at 4.5 years, but at the expense of increased pituitary deficiencies and oculomotor nerve palsies.[132] Claims of efficacy of proton treatment must be validated with longer-term toxicity outcomes and in the context of well-designed studies. Currently, proton beam radiotherapy cannot be recommended as standard treatment for pituitary adenomas.

KEY POINTS

- The use of heavy-charged particles has not demonstrated any clear benefit over conventional photon (fractionated) therapy; long-term data are required to assess if proton therapy is associated with lower risk of sequelae.

SUMMARY

Radiotherapy remains an effective treatment in achieving tumor and hormonal control in patients with pituitary adenomas. Differences in the efficacy and toxicity of FSRT and SRS for treatment of pituitary adenomas are suggested by the comparison of reported outcomes in retrospective reviews, many of which are small. However, with differences in patient selection for SRS and fractionated treatment, comparisons between delivery methods are difficult, if not impossible, to make. Because fractionated treatment has been used for decades, information about the long-term effects of SRS is not yet as mature, and long-term data are largely missing.

In the absence of randomized data, technical developments in radiation delivery are assumed to be of benefit and are adopted into practice. However, when there are more substantial changes to treatment, such as changes in dose and fractionation, outcomes should continue to be monitored to ensure that the use of alternative treatment scheduling frequently dictated by technologies employed is as effective and safe as more traditional approaches. Early reports of novel technologies claiming superiority other than demonstrating feasibility should largely be ignored, as only long-term data on efficacy and toxicity should lead to changes in practice. The decision as to whether to use a fractionated versus a radiosurgical approach is generally based on the tumor characteristics and the relationship between the target and nearby normal tissue, but, when either option can be delivered within the dose constraints, available data currently suggest that either approach may be offered safely.

REIRRADIATION

Reirradiation for progressive or recurrent disease is considered with caution because of the higher risks of radiation-induced injury resulting from the late effects of treatment on the optic apparatus, cranial nerves, and vasculature, as well as on the normal brain tissue. However, reirradiation using fractionated conventional stereotactic methods is feasible and effective in achieving tumor control and recovery of tumor-related symptoms such as visual improvements, with acceptable toxicity when delivered after a minimum 3- to 4-year gap since the first irradiation and if the primary radiotherapy treatment was delivered to doses below the radiation tolerance of the central nervous system.[133] Risks of reirradiation include hypopituitarism, temporal lobe injury/radionecrosis, and an increased risk of radiation-related tumors, including pituitary carcinoma.[134-136] Although reirradiation can improve vision, the risk of optic neuropathy is higher after reirradiation, and careful counseling regarding the risks must be undertaken.

Radiosurgery has been used after previous radiotherapy, with some success in achieving hormonal control in acromegaly, although the duration of benefit is not known, and retreatment carries significant risk.[137]

CONCLUSIONS AND FUTURE DIRECTIONS

In the absence of randomized data, the comparison of radiotherapy treatment approaches relies on retrospective studies, with variation in populations and indications for treatment, nonstandardized follow-up protocols, varying duration of follow-up, and incomplete outcome reporting. Because of the heterogeneity of published studies, conclusions are often based on systematic reviews and quasi metaanalyses, which, despite combining data into larger cohorts, cannot improve on the limited quality of the initial datasets and therefore suffer from the same problems. The quality of the publications is also highly variable, and the impact of missing data, which are likely to have considerable impact on outcome, is rarely, if ever, discussed.

Despite the significant caveats, the published data show that radiotherapy is an effective treatment for functioning pituitary adenomas and NFPAs, with good long-term tumor and hormonal control. Long-term side effects of fractionated radiotherapy are acceptable, although improvements in late side effects continue to be sought.

The development of high-precision stereotactic treatment methods and hypofractionation with radiosurgery has coincided with the move away from routine postoperative radiotherapy to all patients, and the long-term outcomes of radiotherapy treatment using stereotactic methods would be expected to compare unfavorably with the results from fractionated conformal series. While the tumor control rates and hormonal control rates appear to be slightly lower, the results are comparable to those from studies where all patients were treated. The toxicity of radiosurgery for small tumors is comparable with that of fractionated treatments used for tumors of all sizes, with the current exception of second brain tumors. Currently, there is no clear evidence of superiority for one radiation method over another, if the tumor size and position allow the dosimetric constraints to be met.

INTRODUCTION

One of the most common reasons for referral to a pediatric endocrine clinic is to evaluate an infant/child/adolescent for short stature in relation to their calendar or chronological age (CA). Allowing for the relatively wide range of normal variability in stature and rate of growth in stature, several clinical conditions suggest a need for appropriate therapy, even if the latter is just reassurance.

Nutritional status and the psychosocial concomitants of short stature or delayed maturation are inextricably entwined in such evaluations. These issues are seemingly more apparent during the interval of puberty, when the youngster stands out relative to same age peers who have already begun pubertal maturation. Of relevance, socialization and sports participation often track with maturational (biological) age to a greater degree than CA.

Evaluation of children for short stature and/or delayed maturation begins somewhat differently for boys and girls, and the differential diagnosis may be quite different after allowing for normal variation in growth and maturation. From the perspective of both children and parents, it appears that the psychosocial aspects of being short affect boys more so than girls, which often motivates earlier evaluation of boys by a pediatric endocrinologist.

The process of "growing up" among children and youth is often taken for granted. The process is in fact more complex and involves three interacting, though distinct, processes: physical growth, biological maturation, and behavioral development.[1] The latter is often subsumed in the term "socialization," which is specific to a culture. The three processes occur simultaneously and dominate the daily lives of children and adolescents (and their families) for the first two decades of life.

Growth refers to the increase in size of the body as a whole and of its parts. As children grow, height and weight increase. In addition, different segments of the body, e.g., extremities and trunk, grow at different rates and at different times, resulting in altered body proportions. Weight is a heterogeneous mass that includes a variety of organs, the skeleton, musculature, and fat or adipose tissue.

Maturation refers to progress towards the biologically mature state (i.e., maturity). Maturation occurs in all bodily organs and systems, but maturity varies with the individual biological system considered. Sexual maturity implies fully functional reproductive capability. Skeletal maturity is a fully ossified adult skeleton. Maturation of the nervous and endocrine systems are major factors that influence somatic growth and sexual and skeletal maturation. The processes of physical growth and biological maturation are the focus of this chapter. They occur concurrently and are related, and vary in *tempo* and *timing*. The former refers to the rate at which the processes progress from infancy through adolescence, while the latter refers to the ages when specific events or milestones occur. Indicators of growth may also be used in deriving estimates of maturation.

Although not a focus of this chapter, development refers to the acquisition and refinement of behaviors expected and in many instances set by society. As children experience life at home, neighborhood, school, church, sports, recreation, and other community activities, they develop cognitive, social, affective, moral, motor, and other behaviors expected by society, i.e., behavioral competence in a variety of domains. Proficiency in motor or movement behaviors, i.e.,

TABLE 17.1 **Comparison of features of the Silver-Russell and Beckwith-Wiedemann Syndromes**

Feature	Silver–Russell	Beckwith–Wiedemann
OMIM #	180860	130650
Epigenetic locus Imprinting center (control of fetal growth)	11p15.5	11p15.5
Major clinical findings (heterogeneous)	Severe intrauterine growth restriction; small for gestational age without catch-up growth; conserved head circumference (relative macrocephaly); triangular facies; skeletal asymmetry; feeding difficulties, especially early in life; some with early adrenarche or puberty; high probability of metabolic syndrome as adults	Macrosomia (90%); macroglossia; abdominal wall defects (omphalocoele); visceromegaly (kidneys, liver, pancreas); childhood embryonal tumors (Wilms tumor and hepatoblastoma most common)
Frequency	1/30,000–1/100,000 (may be higher given difficulty in diagnosis); diagnosis based on clinical findings—clinical scoring system	1/10,300–1/13,700; diagnosis based on clinical findings
Metabolic consequences	High probability of metabolic syndrome as adult	Neonatal hypoglycemia
Heritability		~85% sporadic

running, jumping, hopping, etc. is related in part to growth, including size and body composition. This association is especially apparent during pubertal maturation and the growth spurt.

Prenatal Considerations

Although this chapter focuses on the postnatal years and largely adolescence, it is important to understand the prenatal background of these processes. In this context, the potential role of maternal characteristics and behaviors related to energy intake and weight gain, alcohol consumption, smoking, and drug use have received attention. Evidence has accumulated over the past 30 to 40 years supporting the concept that events occurring prenatally condition postnatal growth and maturation, and perhaps adulthood and aging. This is often set in the context of the "fetal origins hypothesis" (Barker hypothesis), which emphasizes associations between birth weight, as a marker of fetal growth, and risk for several chronic, degenerative diseases in adulthood. The hypothesis highlights interactions among factors that influence prenatal growth and factors in the postnatal environment, especially diet and stress, which may have consequences of disease many decades after the original insult.

Normal fetal growth may be divided into two epochs. The first, roughly the first trimester of pregnancy, consists of proliferation, organization, and differentiation of the embryo. The second, comprising the remainder of pregnancy, involves continuing growth and functional maturation of the different tissues and organs of the fetus.[2] All of the following must be working simultaneously and in a coordinated fashion: genetic programming, placenta, integrity of the materno-placento-fetal unit, and an adequate supply of nutrients and oxygen, along with the proper hormonal milieu (fetal and maternal).

The hormonal requirements for growth differ markedly from the pre- to postnatal periods. *In utero* the Insulin-like growth factor (IGFs) and insulin predominate, without much effect of growth hormone (GH) or thyroid hormone. Congenitally GH- or thyroid hormone–deficient fetuses have a normal or near-normal birth length. The maternal hormone production and blood flow are regulated by the placenta and contribute to the differentiation and subsequent growth of the embryo/fetus. Predominant among the substrates are glucose and amino acids, which depend on their transport proteins. Fatty acid delivery meets the requirements for cell membrane synthesis, for other hormones, and as a source of total energy.

Rodent models that lack IGF-1, IGF-2, or the IGF-1 receptor have reduced birth weights, and deletion of the IGF-1 type 1 receptor gene results in greater growth retardation that deletion of *IGF-1* or *IGF-2* alone (in addition to being lethal), suggesting a role for both IGF-1 and IGF-2 in prenatal growth. IGF-1 and IGF-2 act through the IGF-1, insulin, and IGF-2 receptors, and IGF-2 is approximately equal in importance to IGF-1 for fetal growth, with each contributing approximately 40%.[3]

Six IGF-binding proteins (IGFBPs) regulate the amount of free IGF available and are regulated in turn by IGFBP proteases. High levels of IGFBPs have been associated with fetal growth inhibition, likely from sequestration of fetally derived IGF-1.[4,5] IGFBP-3 also prolongs the half-life of IGFs in circulation, and levels are reduced in the cord serum of small for gestational age (SGA) fetuses.[5]

Pregnancy-associated plasma protein A (PAPP-A), which cleaves IGFBP-4, increases free IGF availability,[6] and low first-trimester PAPP-A levels in pregnant women are associated with lower birth weight.[7]

Placental IGF-2 is an important factor for fetal growth and nutrient delivery. Disturbances in its production or action may lead to the asymmetric growth retardation of Silver–Russell syndrome, whereas overexpression of *IGF-2* leads to a large placenta and the Beckwith–Wiedemann syndrome of overgrowth (Table 17.1).

In addition to IGFs, insulin influences fetal growth through its anabolic effects on carbohydrate and protein metabolism. Infants of diabetic mothers and children with Beckwith–Weidemann syndrome (with hyperinsulinism) have excessive fetal growth, and those with pancreatic agenesis have poor fetal growth. Mutations in the insulin receptor and in IRS-1, a downstream molecule in the signaling pathways of both IGF-1 and insulin receptors, are associated with suboptimal fetal growth and insulin resistance.[8]

As noted, understanding the regulation of fetal growth has assumed particular importance because of potential links between prenatal growth and later disease. Strong experimental evidence in animal models indicates that an adverse fetal environment, as reflected in birth size, can lead to poor health outcomes in adults, likely through an epigenetic mechanism.[9,10] Diverse causes of poor fetal growth (including maternal undernutrition or glucocorticoid exposure) can have similar deleterious effects on postnatal health (including hypertension, cardiovascular disease, and glucose intolerance). Considerable human data support such a "developmental origins of health and disease" model.[9-12] The risks for insulin resistance, diabetes, and visceral adiposity are particularly high in SGA infants with rapid postnatal "catch-up" growth.[9,13] Girls with this condition may undergo slightly early (not precocious) but quite rapid pubertal maturation, losing a significant proportion of their pubertal growth (height) spurt.

KEY POINTS

- The prenatal environment is critical to the fetal (developmental) origins of adult diseases—developmental origins of health and disease. These conditions are one of the drivers of noncommunicable, especially cardiovascular, disease in older adults.

Chronological Age

Prior to discussing growth and maturation, it is essential to address CA, which is the point of reference in studies of growth and maturation *per se*, and also in the clinical context. CA is calculated as the difference between the date of measurement/observation and date of birth, and is ordinarily expressed as decimals of the whole year. Use of whole years, i.e., 6 years of age, can be misleading.

Growth Status

Growth status refers to the size attained at the date of observation. Height (length from birth to 2 years) and weight are the primary indicators of growth status. Height, or more appropriately standing height, is the distance from the standing surface to the top of the skull. Sitting height, the distance from the flat sitting surface to the top of the skull, is often measured and provides information on upper body segment length. Standing height minus sitting height provides an estimate of leg or lower body length (Fig. 17.1). Weight is a measure of body mass, which is heterogeneous in composition; it is generally partitioned into its fat and lean components. The latter includes two major components, lean tissue mass (LTM) or fat-free mass (FFM) and bone mineral content (BMC), while the former is expressed as fat mass (FM) or as a percentage of body weight (% FM).

Measurements of weight, height, and sitting height should be made by trained individuals using standard techniques (Fig. 17.1).[14] Quality control is essential; it refers to the accuracy and reliability of measurements, and to measurement variability within (intraobserver) and between (interobserver) technicians.[15]

Height and weight increase gradually through childhood, increase at an accelerated rate during adolescence (growth spurt), and then slowly increase into late adolescence. Growth in height stops in the late teens or early twenties, whereas weight often continues to increase. FFM, LTM, and BMC have a growth pattern like height and weight, and each has an adolescent spurt, while FM increases more gradually with CA. Relative fatness (% fat) increases during childhood, but declines during adolescence in males and continues to increase at a slower pace in females during adolescence. The decline in % fat in males is due to the rapid growth in FFM (Figs. 17.2 and 17.3).[1]

Growth Charts. The growth status of a child or group of children is commonly compared to growth charts, which are a reference of comparison. The World Health Organization (WHO)[16] defines a reference "...as a tool for grouping and analyzing data and provides a common basis for comparing populations." Several growth charts for height and weight are available. It is important to note that *reference values* are not *standards*. A standard is prescriptive and suggests the way things *ought* to be, and as such has an associated value judgment. The WHO has produced a set of standards for the growth of infants and children up to the age of 5 years; however, there are several countries in which infants and children grow in slight excess of them, lessening their utility (Fig. 17.4).[17]

Height and weight charts commonly used in the United States are based on surveys of nationally representative samples of children and youth between the 1960s and 1994, except for length at birth, which are from surveys in two states (Fig. 17.4).[18,19] Heights of American children and youth did not differ significantly between the 1960s and 1990s; however, body weights of children greater than or equal to 6 years increased significantly between surveys in 1976 to 1980 and 1988 to 1994.[18,19] The gain in body weight from the late 1970s through the mid-1990s was viewed as undesirable from a public health perspective, so that in developing the growth charts for body weight, the values from 1988 to 1994 were not used. The charts for weight are thus to some extent a standard, or criterion-referenced, in that public health authorities decided on levels of weight that are presumably conducive to better health. Although the US growth charts are seemingly somewhat dated, changes in the heights of American girls and boys have been relatively small across several national surveys spanning 2002 through 2014, although weights have increased over time.[20-23]

Sex-specific charts for recumbent length and weight are provided for children from birth to 3 years; the data for length at birth are from surveys in two states (Fig. 17.4).[18,19] Corresponding charts for standing height and weight are provided for children and youth from 2 to 20 years of age (Fig. 17.4).

Many other countries have designated "country-specific" growth curves to better represent their present status. These are reference charts and may deviate from the standards of the WHO. For example, in Indonesia the WHO charts significantly overestimate the true prevalence of undernutrition, because healthy children 0 to 5 years are short and slim when plotted on the WHO charts, with mean z-scores of approximately -2.0, indicating that approximately 50% of the children are stunted (Fig. 17.5).[24]

Weight for height, expressed as the body mass index (BMI, [weight (kg)/ height (m^2)]), is commonly used to evaluate the weight status of children and youth spanning the spectrum from low (often labeled as underweight or extreme thinness) through excess (labeled as obesity) weight for height. The BMI is often considered an indicator of adiposity or fatness, but it is not a measure of body composition. Moreover, the BMI is significantly correlated with both FFM and FM in normal-weight youth[25] and is perhaps more closely associated with LTM rather than FM among relatively thin youth (Table 17.2).[26]

Several charts of cutoff values of the BMI designed to define the weight status of an individual are available. The focus, however, is largely on overweight and obesity. The charts for American children and youth (see above)[18] and those recommended by the WHO[27] present specific percentiles for BMI. The WHO charts were developed from the WHO growth standards for children from birth to 5 years of age and the 1977 United States reference data at older ages using updated statistical methods.[27] The International Obesity Task Force (IOTF), in contrast, used adult criteria to define cut-points for overweight and obesity,[28] and also for several levels of thinness.[29] Data for nationally representative samples of children and adolescents aged 2 to 18 years from Brazil, Great Britain, Hong Kong, the Netherlands, Singapore, and the United States were used to develop the IOTF criteria.[28,29] In establishing the cutoff points, curves were mathematically fitted to pooled BMI data from the six countries so that they passed through adult criteria to define overweight (25.0 kg/m^2) and obesity (30 kg/m^2) and three grades of thinness (16.0, 17.0, and 18.5 kg/m^2) at 18 years of age.[30]

Given the variety of criteria for evaluating weight status with the BMI, there is a need for a critical evaluation of the suggested cutoffs. For example, US and IOTF cut-points for BMI differ for obesity, but are reasonably similar for overweight. One can also inquire into the

Growth Rate

The increment in height or weight between two observations provides an estimate of growth rate or velocity or *tempo* of growth. Measurements, however, are not always taken at prescribed dates or intervals. As such, observed increments require adjustment for the actual interval between measurements.

Increments are influenced by technical errors of measurement at each observation, and also by diurnal variation (variation during the course of a day). Heights measured in the morning, shortly after arising, are generally taller than those taken later in the day. The "shrinkage" in height is attributed to the compression of the intervertebral discs associated with gravity and physical activity. Increments in height also show seasonal variation in some parts of the world. Evidence from several studies in North America and Europe indicates a greater childhood growth rate in height during the spring compared with the fall.[31] Allowing for measurement variability *per se* and diurnal and seasonal variation, estimates of growth rates over short durations, e.g., 3 or 6 months, must be interpreted with care.

Growth rates (cm/year, kg/year) are presented as velocity curves, which differ in shape from the curves of size attained at different ages described above (Fig. 17.2). The velocity curve for height (length among infants) indicates a brief acceleration in rate of growth after birth, which is followed by a constantly decelerating rate growth in stature during infancy and childhood, i.e., the child is getting taller, but at a constantly slower rate. The growth rate reaches its lowest point ("prepubertal dip") just prior to the initiation of the adolescent spurt. The lowest point is labeled as the age at takeoff of the adolescent spurt, because this is the point at which the velocity curve begins to accelerate. In contrast, after deceleration during infancy and the second year, rate of growth in weight occurs at a slight but constantly accelerating rate until the adolescent spurt (Fig. 17.4).

Rates of growth in both stature and weight accelerate during the adolescent spurt. Acceleration in height occurs prior to that in weight, and maximal velocity of growth in height (peak height velocity [PHV]) occurs earlier than that for weight (peak weight velocity). After peak velocity of growth in height is attained, the velocity of growth in height gradually declines, and growth in height eventually ceases in late adolescence. Estimated PHV occurs, on average, approximately 2 years earlier in girls than in boys. Girls stop growing in stature by approximately 16 years, on the average, whereas boys continue to grow for another 2 or 3 years. Velocity of growth in weight also declines after the peak, but often remains positive into the early twenties.

Reference values for annual or semiannual height increments are available for children and youth in the Fels Longitudinal Study from birth to 18 years,[32,33] and have been more recently reported for samples of Black and White American children and youth 6 to 18 years of age.[34] Reference values for short-term increments in heights of British children 7 to 10 years of age are also reported.[35]

In addition to the well-defined adolescent spurt, some children show a small growth spurt in stature and weight (increase in velocity of growth) several years before the onset of the adolescent growth spurt. The midgrowth spurt usually occurs between 6.5 and 8.5 years of age, occurs more frequently in boys than in girls, and does not appear to show a sex difference in timing.[36-38] The midgrowth spurt reflects biological variation among individuals, but the frequency of measurements in childhood is an additional factor. Children are usually measured annually during childhood "well-child" visits, and such an interval may not be sufficiently sensitive to detect the change in velocity of growth that defines the midgrowth spurt.

Maturity Status

Maturity status refers to the level or state of maturation at the time of observation. Indicators of skeletal and pubertal maturation are used most often.

Skeletal Maturity Status

Skeletal maturation is generally estimated as skeletal age (SA) based on the bones of the hand and wrist viewed on a standard radiograph. Each bone goes through a series of changes from initial ossification to adult morphology. The changes provide the basis for assessing skeletal maturation based on the assumption that specific features of each bone as observed on a radiograph occur regularly and in an irreversible order, and as such provide a record of the progress of each bone towards maturity. Other parts of the skeleton, e.g., knee and foot and ankle, as well as the hemiskeleton as an "integrated" determination by the time of appearance of various centers of ossification, have also been used to derive estimates of SA.[39]

Methods of Assessment. Three methods are commonly used to estimate SA of the hand-wrist. Each method calls for the hand-wrist radiograph of a child to be compared to specific criteria; ratings are subsequently converted to an SA *that is specific to the method*. Indicators of maturity defined for specific bones in each method suggest discrete steps in a continuous process.[1,40]

The Greulich–Pyle (GP) method[41] is an extension of the method initially described by Todd.[42] The method was developed on upper–socioeconomic status White American children from Cleveland, Ohio. Accordingly, each individual bone of the hand-wrist is rated relative to sex-specific standard plates representing specific SAs from infancy through adolescence. The method often requires interpolation between the standard plates. An SA is assigned to each bone, and the median of the SAs is the estimate of SA for the child. In practice, however, the GP method is often applied by comparing the radiograph as a whole to the pictorial standards and assigning the SA of the standard to which the radiograph most closely matches. As such, variation in level of maturity among individual bones may be large and is often overlooked. By convention, the left hand and wrist are used.

The Tanner–Whitehouse (TW) method[43] was developed on British children in the Harpenden Study. Specific criteria or stages spanning initial appearance (ossification) to maturity were described for each of 20 bones in the hand-wrist: the radius, ulna, and metacarpals and phalanges of the first, third, and fifth digits (long bones) and the carpals, except the pisiform. A maturity score was also assigned to each stage for each of the 20 bones. The scores assigned to each of the 20 bones are summed, with the seven carpals and 13 long bones each contributing

50% to the skeletal maturity score; the score for the 20 bones is then converted to an SA using sex-specific tables.

The first revision of the method, TW2,[44,45] did not modify the criteria for maturity indicators; however, the final stages for five carpals and the radius and ulna were eliminated. In addition to the original SA based on 20 bones (TW2 20 Bone SA), two other SAs were provided, an SA based on the seven carpals (TW2 Carpal SA) and an SA based on the radius, ulna, and short bones (TW2 RUS SA). The maturity scores assigned to the stages for each bone are sex-specific and vary for the 20-bone, carpal, and RUS protocols. The sum of the maturity scores for 20 bones, the seven carpals, and the 13 long bones is converted to an SA using sex-specific tables.

The most recent version, TW3,[46] retained the RUS (TW3 RUS) and carpal (TW3 Carpal) SAs but eliminated the 20 Bone SA. The tables for converting carpal maturity scores were not modified; the reference for TW3 Carpal SA was the original British series. In contrast, the tables for converting the RUS maturity scores to SAs were modified. Reference values for TW3 RUS SA were based on a composite of the original British series and samples of Belgian (Flemish), Italian, Spanish, Argentine, Japanese, and American children and adolescents surveyed in the late 1960s through the mid-1990s; the American sample was from an upper–socioeconomic status area in the Houston region (Texas). Ages at attaining skeletal maturity with the TW3 RUS protocol were also lowered from 16.0 to 15.0 years in girls and from 18.2 to 16.5 years in boys.

The Fels method[47] was based on participants in the Fels Longitudinal Growth Study of children from middle class families in south-central Ohio. The method specifies criteria for the radius, ulna, carpals, and metacarpals and phalanges of the first, third, and fifth rays. Grades are assigned to each bone depending on age and sex. Ratios of linear measurements of the widths of the epiphysis and metaphysis of the long bones are also used, and the presence (ossification) or absence of the pisiform and adductor sesamoid is noted. Grades assigned to the individual bones and width measurements are entered into a program that calculates SA and its standard error; the latter provides an estimate of the error of the assigned SA, which is not available with the GP and TW methods.

Skeletal Age. The SA assigned to the radiograph of an individual represents the CA at which a specific level of maturity of the hand-wrist bones was attained by the *reference sample* upon which the method of assessment was developed. An individual who has attained skeletal maturity is simply noted as mature. Of relevance, the individual is skeletally mature at the time of observation; when he/she attained the skeletally mature state is not known. As such, *an SA is not assigned when the hand-wrist radiograph indicates skeletal maturity*.

SA is ordinarily expressed relative to CA. The difference between SA and CA (SA minus CA) is often used as to indicate maturity status, i.e., early or advanced, average or "on time," and late or delayed.

SAs derived with the different methods, though related, are not equivalent, as criteria, methods, and reference samples differ. The GP, TW 20 Bone, and Fels methods each include the carpals, while the TW2 and TW3 RUS protocols are limited to the long bones (radius, ulna, metacarpals, and phalanges). SAs based on the GP and Fels methods, and three versions of the TW method (TW2 20 Bone, TW2 RUS, TW3 RUS) in a sample of German boys 6 to 16 years of age[48,49] are summarized in Table 17.2. Heights of the boys matched, on average, medians of current US reference data. The original study used the GP method, but the radiographs were made available and were assessed with the GP (bone by bone), Fels, TW 20 Bone and TW2 RUS methods.[50] The TW2 RUS scores were subsequently converted to TW3 SAs (Malina, unpublished).

Standard deviations for SAs were three to four times larger than those for CA, highlighting variation in skeletal maturity status within a *single-year* CA group (Table 17.3). Mean SAs with each method varied and overlapped within each CA group, except for consistently lower SAs with the most recent TW revision. Beginning at 9 to 10 years, TW3 RUS SAs were consistently lower than TW2 RUS SAs. This same trend was noted in a large series of youth soccer players.[51] The trends in comparisons among methods were generally consistent with observations of GP, Fels, and TW2 SAs in a clinically normal sample of 23 boys followed from 8 to 15 years.[52]

As noted, TW3 RUS SAs are systematically lower than TW2 RUS SAs beginning at about 10 years of age. The rationale for assigning lower SAs for the same RUS score with TW3 compared with TW2 was to accommodate secular change.[46] Although secular changes in height are evident in early childhood and continue through puberty,[1,53-54] modifications in SAs assigned to the same RUS maturity scores in boys (i.e., lower SA for the same maturity score with TW3) were only apparent beginning with SAs of about 10 years. Of relevance, secular increases in height were not necessarily accompanied by accelerated maturation between 1960 and 1980 in Belgium[55,56] and between 1980 and 1997 in the Netherlands.[57]

Although not indicated in Table 17.3, a number of boys were skeletally mature, especially with the TW method (one each at 14 and 15 years, and five at 16 years) compared with the GP (two at 16 years) and Fels (one at 16 years). Numbers of skeletally mature boys were larger at 17 years (GP 9, Fels 11, TW 17). The discrepancy between the GP and Fels methods and the TW method regarding skeletal maturity of the hand-wrist relates to the criterion for the final stage of the radius and ulna, respectively. With the TW method, the final stage for the radius and ulna is simply "fusion of the epiphysis and metaphysis has begun."[46] With this criterion, the interval between onset and completion of epiphyseal union of both bones is not considered. Many youth are thus classified as skeletally mature even though the process of fusion in each bone is still in progress. On the other hand, onset through *complete* fusion of the distal radius and ulna are used in the GP and Fels methods.

SA, or more colloquially "bone age," has been indicated for CA verification in medicolegal contexts for many years, and also in some youth sport competitions. Evidence from a review focused on male soccer players and female artistic gymnasts[58] indicates the following. Among adolescent male soccer players (and likely male athletes in other sports), a significant number will be identified as older than a CA cutoff due to advanced skeletal maturity status when they in fact have a valid CA. SA assessments of soccer players were generally comparable to magnetic resonance imaging (MRI) assessments of epiphyseal-diaphyseal union of the distal radius, which have been recommended for age verification for international competitions among U-17 soccer players.[59,60] Both protocols indicated a relatively large number of false negatives among youth players aged 15 to 17 years. Among adolescent female artistic gymnasts, a significant number of age-eligible gymnasts would be identified as younger than the CA cutoff due to later skeletal maturation, when in fact they have a valid CA. On the other hand, there is also the possibility of false positives—identifying athletes as younger than the CA cutoff due late skeletal maturation, when in fact their birth certificates or passports indicate a CA older than the cutoff.

Given the available data on the potential for false negatives and false positives, SA is therefore not a valid indicator of CA. The situation is more complicated for CA verification in the context of immigration regulations. Given the variation in SA within single-year CA groups, and also variation in SAs based on currently available methods, use of SAs as an indicator of CA for the purpose of immigration has major limitations.

TABLE 17.3 Skeletal Ages With Five Different Methods of Assessment in Boys 8–16 Years of Age

			SKELETAL AGES, YEARS									
	CA, yrs		GP		Fels		TW2 20 Bone		TW2 RUS		TW3 RUS	
N	M	SD	M	SD	M	SD	M	SD	M	SD	M	SD
26	8.4	0.3	8.3	0.9	8.1	0.9	8.3	0.9	8.0	1.0	8.0	0.9
23	9.5	0.3	10.1	1.0	9.6	1.0	9.8	0.9	9.8	1.2	9.4	0.9
22	10.5	0.3	10.2	1.0	9.7	1.0	10.1	1.2	9.9	1.1	9.5	0.8
20	11.5	0.2	11.0	0.8	10.7	1.2	11.2	0.9	11.3	1.2	10.5	0.9
31	12.4	0.3	12.1	1.0	12.2	1.5	12.6	1.5	12.6	1.6	11.6	1.3
22	13.5	0.3	12.8	1.0	13.0	1.4	13.5	1.4	13.5	1.6	12.3	1.5

20	15.4	0.3	14.9	0.8	15.4	0.9	15.8	0.8	15.9	0.9	14.9	1.0
10	16.5	0.3	15.8	0.8	16.5	0.8	16.8	0.8	17.0	0.8	16.0	0.8

CA, Chronological age; *GP*, Greulich–Pyle; *TW*, Tanner–Whitehouse; *RUS*, radius, ulna, and short bones; *N*, number of subjects; *SD*, standard deviation; *M*, mean.

Other Protocols. Given advances in technology, several new protocols for the assessment of the skeletal maturity of the bones of the hand and wrist have been proposed. The procedures are generally based upon the GP and TW methods and are largely designed for clinical use. These include ultrasound assessment of the maturity status of the distal radius and ulna, with SA scaled relative to the GP method,[61,62] although its validity has been questioned.[63] Assessment of SA based on dual-energy x-ray absorptiometry scans of the hand-wrist have also been proposed.[64-66] Automated methods are also available.[67-69] The BoneXpert method[68] is unique in that it derives an "intrinsic" bone age based on bone borders (shapes) and wavelet texture of images of 15 bones: radius, ulna, and the five metacarpals and eight phalanges in the first, third, and fifth fingers. The "intrinsic" bone ages are subsequently calibrated to GP and TW RUS SAs.

Overview of Skeletal Age. SA can be used across approximately the first two decades postnatally; in contrast, other maturity assessments are limited to puberty and adolescence (see later). Estimates of SA by each method are reasonably precise and reliable, although intra- and interobserver variability in assessments is rarely reported. Use of SA is also criticized, because specific training is required to learn the protocol(s): this is a shallow criticism, as other protocols also need specific training. Major limitations of SA are the expense associated with the radiographs *per se* and radiation exposure, and also the limited availability of individuals familiar with the details of the different methods of assessment. With modern technology, exposure to radiation presents minimal risk at 0.001 millisievert, which is less than natural background radiation and radiation exposure associated with the equivalent of viewing 3 hours of television per day.[70,71]

The different methods for the assessment of SA are based largely on samples of European ancestry, although the TW3 RUS protocol included data from samples of Argentine and Japanese ancestry in converting maturity scores to SAs (see earlier). Nevertheless, applications of the GP and TW protocols show ethnic variation in SA.[72-78] Applications of the Fels method to youth of different ethnic groups are apparently not available, except for a study of indigenous school children in Oaxaca, southern Mexico.[79] Of potential relevance, identification of the ethnicity of youth in some countries is not permitted.

Secondary Sex Characteristics

Secondary sex characteristics in males include pubic hair (PH), genitalia (G; penis, scrotum, testes), testicular volume, voice change, and facial and axillary hair, while those in females include PH, breasts (B), axillary hair, and menarche.[1,80] Facial hair and voice change in boys and axillary hair in both sexes are also secondary sex characteristics, but they generally develop late during puberty and are not widely used.

Pubertal Stages. The five stages of PH, G, and B described by Tanner[81] are commonly the reference in assessing pubertal status (Fig. 17.6). The stages generally follow the criteria of earlier studies of Reynolds and Wines.[82,83] Stages are labeled PH1 through PH5, B1 through B5, and G1 through G5. Stage 1 of each characteristic indicates the prepubertal state, an absence of overt development, although hormonal changes that trigger puberty may already be underway. Stage 2 marks the overt development of each characteristic; B2 and G2 are typically the first overt signs of the transition into puberty, but PH2 may precede B2 and G2 in some youth. Stages 3 and 4 mark progress in pubertal maturation, and the respective stages are sometimes labeled as mid- and late-puberty. Stage 5 indicates the mature state (Fig. 17.6).

The stages are discrete categories unique to PH, B, and G. A youngster is either in a stage or not in a stage at the time of assessment; there are no intermediate stages. Moreover, stage at time of assessment provides no information on when the youngster entered the stage (timing) or how long he/she has been in the stage, related to the *tempo* of maturity.

It is important to emphasize that the stages of PH and B are unique to girls, and the stages of PH and G are unique to boys. *The stages are not equivalent*, i.e., B3 ≠ PH3, G3 ≠ PH3, B3 ≠ G3, PH3 in girls ≠ PH3 in boys, and so on. The term "Tanner stages," unfortunately, is often used without indicating the specific characteristic(s) that was (were) assessed.

Direct assessments of the stage of pubertal status are made at clinical examination. Self-assessments are often used in nonclinical settings; they require privacy, good-quality photographs of the stages, simplified descriptions, and a mirror to assist in the process. Some self-assessment scales include pictures or drawings of the stages, as well as questions regarding facial and axillary hair in males and axillary hair and menarcheal status in girls.[1]

There is a need for quality control, including intra- and interobserver reliability in assessment of stages, and concordance between self-assessments and those of experienced assessors. Overall reproducibility by experienced assessors is generally good, with approximately 80% agreement in assigning stages, but lower percentages have been reported.[1]

Accuracy of self-assessments is a concern, but opinions vary depending upon the purpose of the study. Based on self-assessments of pubertal status in three annual visits of girls between 11 and 14 years of age and assessments by trained examiners, it was concluded that "… self-assessment can substitute for examiner evaluation only when crude estimates of maturation are needed."[84] On the other hand, agreement to within one stage was suggested as potentially useful in epidemiological surveys of youth,[85] even though concordance between self- and physician assessments indicated limited accuracy. Concordance between and among self-assessment scales currently in use needs further evaluation.

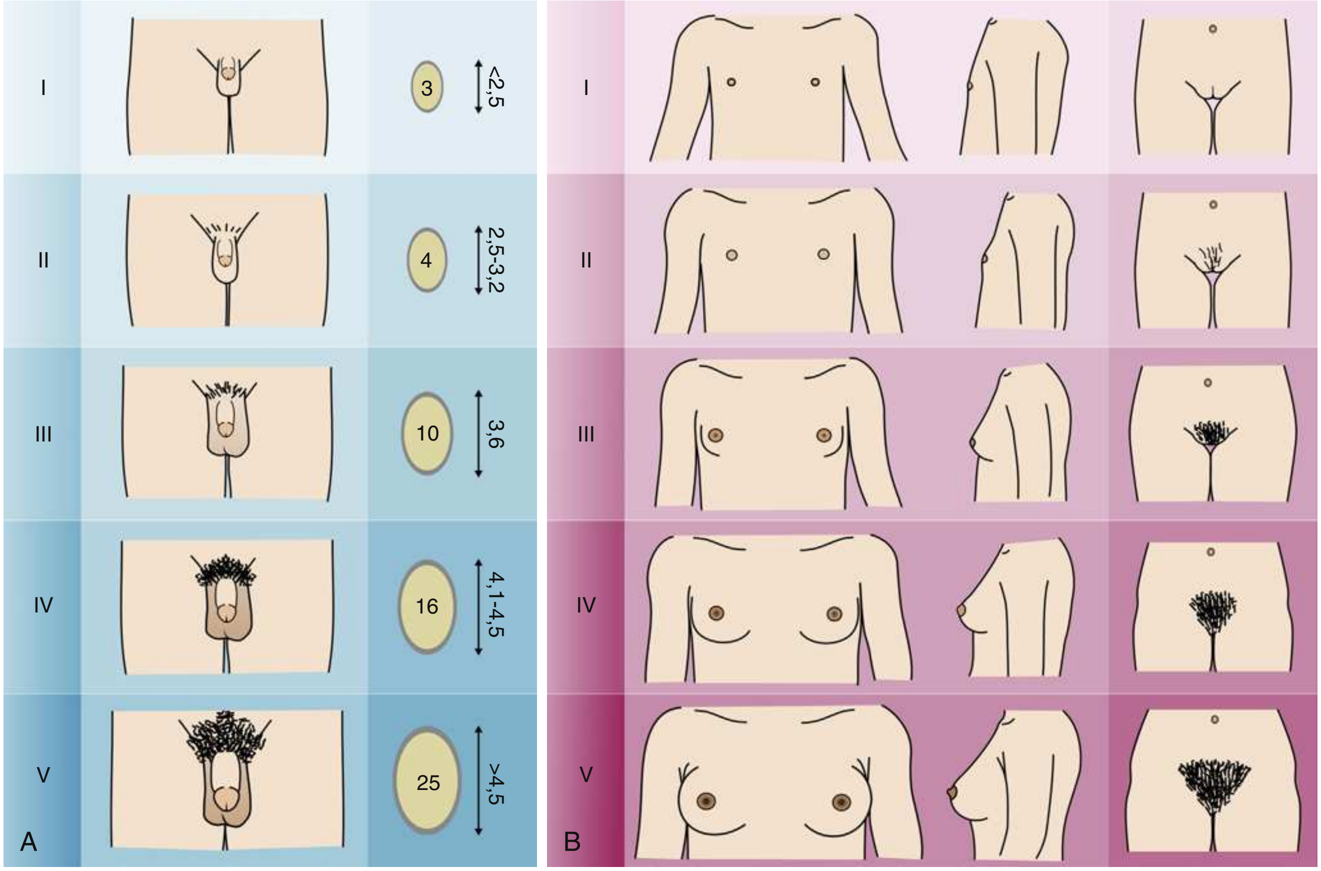

Fig. 17.6 Genital and Pubic Hair Stages at Puberty in Boys and Breast and Pubic Hair Stages in Girls at Puberty. (From Tenbergen G, Wittfoth M, Frieling H, et al. The neurobiology and psychology of pedophilia: recent advances and challenges. *Courtesy: Michal Komorniczak (Poland).*

Assessments of pubertal status are ordinarily done in a clinical context. However, in some cases, researchers are interested in whether a youngster is pre- or postpubertal, i.e., stages 1 and 5, respectively. Others may be interested in early-, mid-, or late- puberty, i.e., stages 2, 3, and 4, respectively. Note, however, as mentioned above, that stages are specific to B and PH in girls and G and PH in boys, and are not equivalent, i.e., B2 ≠ PH2, G3 ≠P H3, etc.

Analytical Concerns. Stages of PH, B, and G are variably reported. Ratings for individuals are periodically combined into a mean of B and PH or of G and PH; there is, however, no biological entity of a "mean stage." The stages are not equivalent and must be considered separately.

Stages are occasionally reported as 3+ or 4+. Note, a youngster is either in a stage or not in a stage; there are *no* intermediate stages. Although mean stages of PH, B, or G by CA at observation are often reported, distributions of stages within each CA group are more informative and relevant.

Youth are also commonly grouped by stage of puberty independent of CA. This is problematic from at least two perspectives. First, stages of puberty vary within a CA group, and second, also vary by CA within a stage. For example, within single-year CA groups of soccer players 11 to 14 years of age, boys in less advanced stages of PH tend to be younger, shorter, and lighter, on average, than players in more advanced stages who are older, taller, and heavier. And, among players grouped by stage of PH, younger boys tend to be, on average, shorter and lighter than older boys who are taller and heavier.[86] Corresponding classifications of girls would likely yield similar results.

Testicular Volume. Testicular volume provides a more direct estimate of genital maturity in boys. The method requires palpation of the testes in order to match their size with a series of models of known volume (Prader orchidometer).[87,88] The ellipsoid models have the shape of the testes and range from 1 to 25 mL; a volume above 4 mL marks the beginning of puberty. The method is used primarily in the clinical setting. Sonography can also be used to estimate testicular volume.[89] In a comparison study, Joustra and colleagues noted that testicular volumes above 5 mL, when evaluated by palpation, are reasonably accurate (compared with the ultrasound method), but may differ greatly below that, when it may be most relevant.[90] For clinical purposes, that may not be so important, just that the testes are prepubertal, but may take on greater importance if gonadotropin treatment is evaluated at minipuberty during infancy.

Menarcheal Status. Although age at menarche is an indicator of maturity timing, whether a girl is premenarcheal or postmenarcheal is an indicator of maturity status. Classifications of girls by menarcheal status are confounded by CA *per se*, i.e., an 11-year-old premenarcheal girl is quite different physically and behaviorally from a 14-year-old premenarcheal girl.

Overview of Secondary Sex Characteristics. Secondary sex characteristics (overt manifestations) are limited to the interval of pubertal maturation. Stages are discrete, but somewhat arbitrary. Direct assessment is often considered invasive, especially outside the clinical setting. Cultural sanctions may limit or prohibit assessment of secondary sex characteristics in some groups. Concordance of clinical and self-assessments is variable and needs further study. Stages of puberty are also variably reported and present analytical concerns.

Maturity Timing

Maturity timing refers to the CA at which specific maturational events occur. The two most commonly used indicators of timing are age at PHV and age at menarche. Both are limited to the adolescent period.

Age at Peak Height Velocity. Age at PHV is the estimated CA at the maximum rate of growth in height during the adolescent spurt. Age at PHV is estimated from serial height measurements of individuals taken annually or semiannually from late childhood through adolescence. Historically, determinations from individual height records were graphically plotted to identify takeoff, peak, and eventual cessation of growth. Mathematical modeling or fitting of individual height records is currently used, and a variety of methods are available.[91] Estimated ages at PHV vary somewhat among methods, but are generally more uniform than estimated peak velocity of growth in height (cm/yr).

Mean ages at PHV are reasonably similar among longitudinal samples of European and North American youth.[1,92] On the other hand, variation in ages at PHV *among individuals* is considerable. In longitudinal samples of British, Swiss, Polish, Belgian, Canadian, and American youth, estimated ages at PHV ranged from 9.0 to 15.0 years in individual girls and 11.1 to 17.3 years in individual boys.[1,93-96]

Age at Menarche. Menarche refers to the first menstrual flow; age at menarche is an indicator of the timing of this pubertal event. In longitudinal studies, girls and/or their mothers are interviewed at each regularly scheduled visit/observation regarding whether or not menarche has occurred. If menarche occurred between visits, further questions pinpoint the specific date/age of the first menstrual flow occurred. This is labeled the prospective method. Prospectively recorded ages at menarche in two longitudinal studies, one of American[94] and one of Polish[96] girls, ranged from 10.77 to 15.25 years and 10.49 to 16.30 years, respectively. Longitudinal studies generally follow subjects across adolescence so that early- and late-maturing girls are included. Depending on ages at which short-term longitudinal studies start and conclude, there is potential risk that early- and late-maturing girls may be excluded.

Ages at menarche based on the prospective method are sometimes confused with estimates based on the *status quo* method. The *status quo* method requires two pieces of information in a cross-sectional sample spanning 9 through 17 years: CA and whether or not menarche has occurred (yes/no). The data are subsequently analyzed with probits or logits to derive a median age at menarche and associated variance statistics for the sample. The *status quo* method is generally used in surveys.

In contrast to the prospective and *status quo* methods, ages at menarche are commonly obtained with the retrospective method, with late adolescents and/or adults asked to recall when they experienced their first menstruation. The method relies on memory, i.e., recall of the age when first menstrual flow occurred. In addition to potential errors with memory *per se*, reported ages are influenced by recall bias (the shorter the recall interval, the more accurate the recall, and *vice versa*) and a tendency to report whole years, typically age at the birthday before menarche.[1]

Estimates of age at menarche based on the retrospective method with samples of young adolescents are biased. Girls who have not yet attained menarche are excluded from the estimates. Some late-maturing girls may not attain menarche until 15 or 16 years, or perhaps later. In a nationally representative sample of US girls, 90% attained menarche by 13.75 years,[97] but 10% of girls attain menarche after this age.

Other Indicators of Timing and Interrelationships. Assuming longitudinal data are available, other potential maturity indicators can be estimated, e.g., age at takeoff of the growth spurt in height, ages at peak velocity for other body dimensions, and ages at attaining specific SAs, stages of pubertal maturation or specific percentages of adult height (see later).

Analyses of ages at attaining several different maturity indicators in two longitudinal series highlight interrelationships among indicators during adolescence.[98-100] Common indicators in the two longitudinal series included ages at PHV and menarche, ages at attaining stages of pubertal development, and ages at attaining specific SAs and percentages of adult height. The analyses indicated a general maturity factor in both sexes underlying the timing of maturity indicators during the interval of the adolescent spurt. The analyses for boys suggested a second factor that loaded on ages at attaining SAs of 11 and 12 years, 80% of adult height, and early stages of PH and genital development, which are characteristic of early puberty. The results also suggested a degree of independence of ages at attaining several maturity markers characteristic of the transition into puberty, i.e., late prepuberty or early puberty.[100] Longitudinal data for 30 boys also indicated considerable variation in SA at the time of pubertal onset (serum testosterone ≥30 ng/dL).[101]

Tempo of Maturation

Tempo refers to the rate at which maturation progresses. Evidence from the Zurich Longitudinal Study indicated the following trends. Intervals (means ± standard deviations) between B2 and B3 and between PH2 and PH3 in Swiss girls were, respectively, 1.4 ± 0.8 years and 1.8 ± 1.0 years, while intervals between G2 and G3 and between PH2 and PH3 in Swiss boys were, respectively, 1.7 ± 1.0 years and 1.3 ± 0.9 years.[102,103] The intervals between the transition into puberty (B2, G2, PH2) and the mature state (B5, G5, PH5) were, on average, 2.2 ± 1.1 years for B and 2.7 ± 1.1 years for PH development in girls, and 3.5 ± 1.1 years for genital and 2.7 ± 1.0 years for PH development in boys. The standard deviations for the transition through puberty for each characteristic approximated 1 year and highlight the variation in *tempo* of maturation of secondary sex characteristics within and among individuals.

Although estimated increments in GP SAs in a longitudinal sample of American children approximated 1 year, variation was considerable and was associated in part with maturity status, i.e., early versus late.[104,105] In a mixed longitudinal sample of White and Black American girls aged 6 to 12 years, mean single-year velocities for TW2 20 Bone SAs varied between 0.66 and 1.14 years/year, and standard deviations varied between 0.33 to 0.52; corresponding mean single-year velocities for boys varied between 0.75 and 1.27 years/year, and standard deviations ranged from 0.32 to 0.60.[73] Single-year rates of skeletal maturation expressed as maturity points per year of the American children[72] overlapped mean rates and ranges for British children.[106] Observations in a longitudinal series of 34 boys suggested that annual increments (years/year) in TW2 SAs (presumably 20 Bone) increased during the interval of puberty and the growth spurt, and that the increments appeared to reach a peak near PHV.[105] Allowing for limited data, it is legitimate to inquire whether a skeletal year equals a chronological year.

Evaluation of Children for Disorders of Growth

One of the most common reasons for referral to a pediatric endocrine clinic is to evaluate an infant/child/adolescent for short stature for his/her CA relative to a reference for the general population. In contrast, relatively few children are referred for tall stature, although the paradigm for evaluation is, in general, similar to that for short children.

Although the most common causes of short stature for calendar age are variations on the theme of normal growth, there are a number of conditions for which evaluation will yield a proper diagnosis and suggest an appropriate therapy; the latter, however, is often a matter of reassurance. Inextricably entwined in evaluations of short stature are nutritional status and the psychosocial concomitants of being short or maturing late. Nevertheless, evaluation of short stature must be viewed in the context of expected age and gender interactions that influence developmental, behavioral, metabolic, biochemical, and hormonal factors, in addition to genetic and environmental factors, including socioeconomic status. Interactions among the preceding are often brought into sharper focus at the time of puberty, especially when peers have begun pubertal maturation. Socialization during puberty, including sports participation, often tracks with biological maturation to a larger degree than CA.

Evaluation of children for short stature and/or delayed maturation begins somewhat differently for boys and girls, although the differential diagnosis may extend beyond the variation in normal growth and maturation. Perceptions and observations of children and parents suggest that the psychosocial aspects of being short affect boys to a greater extent than girls; as such, boys are more often presented to a pediatric endocrinologist for earlier evaluation than girls.

Normal linear growth in stature and weight is generally accepted as a sign of good health. The process of growth is continuous, but not linear, and shows a wide range of variation at different stages of a child's life. Three distinct periods have been formally noted: *infantile,* when the rapid rate of *in utero* growth in length declines during the first year of life; *childhood,* when growth rate is largely steady but declines somewhat just before the pubertal growth spurt begins; and *pubertal,* as the growth spurt occurs.[107,108] Estimated rates of growth in length/height decline from more than 25 cm/year shortly after birth to approximately 12 cm/year at the end of the first year and to approximately 7 cm/year at the end of the second year. Subsequently, growth rate in height varies between approximately 5 and 7 cm/year and declines, on average, slightly until the initiation of the pubertal growth spurt (age at takeoff), when the rate of growth in height accelerates and reaches approximately 9 cm/year in girls and 10.5 cm/year in boys at PHV. After PHV, growth rate declines until growth in height terminates in the late teens or early twenties. Individual children will often cross major percentiles on the growth chart during the first 24 months as they are no longer bound by the constraints of the intrauterine environment and move toward their genetic potential. Of interest, the correlation between birth length and adult height is approximately 0.1, while that between length (height) at 2 years and adult height is approximately 0.7.

Growth disorders may be divided into at least three categories: primary or intrinsic to the growth plate; secondary or due to changes in the milieu of the growth plate, as in hormonal deficiencies; and idiopathic. Most systemic diseases or their treatments will slow linear growth (at least transiently) such that velocity of growth in height is sufficiently reduced that height begins to fall from a previously defined percentile. Allowing for normal variability, the pediatrician becomes concerned when two major percentile lines on the standard growth chart for height (size attained) are crossed (Fig. 17.4). The preceding is more apparent using height velocity charts with due care in estimating growth velocities from sequential measurements (e.g., measurement variability *per se*, adjustment for the interval between observations) (Fig 17.4). The hallmark of this transient slowing of growth is the phenomenon of catch-up growth, i.e., growth in height at a higher than normal rate that allows a child to move upward on the growth chart, usually to the percentile along which he/she was previously growing, after the growth inhibiting factor(s) has (have) been removed.

Full evaluation includes noting chronological and biological age, measurements (and charting) of height (length) and weight, estimates of height velocity, as well as parental heights, personal and family history, physical examination, state of pubertal maturation, and review of different systems. Subsequent laboratory and imaging studies are based on these initial observations.

Growth Charts

Multiple growth charts for height, height velocity, and weight are available. The WHO charts are recommended for international use, while other charts are based on specific countries, regions or ethnic groups (Fig. 17.4). Growth charts can be integrated into the electronic health record and automatically plotted to permit immediate comparison with earlier observations. A secondary benefit of immediate comparison is a reduced risk of inaccurate measurements, as the child can be remeasured if necessary. Nevertheless, appropriately calibrated instruments and care in the measurement process are essential. In addition, a child's record can be evaluated by a growth "algorithm," which can also take into consideration deflection from the midparental target height and perhaps accelerate referral to specialists for children who may require such attention.

There are at least two types of charts: *reference charts* that provide a snapshot of how children are growing relative to the population, and *standards* that provide an estimate of how children *should* grow given optimal nutrition and care. These were noted in more detail earlier.

KEY POINTS

- Maturity status may be determined by physical examination of the secondary sex characteristics, often using the Tanner criteria or by assessing skeletal (bone) age by one of several standardized methods. The timing of certain events and the tempo of maturation are important milestones.

EVALUATION OF CHILDREN WITH SHORT STATURE

Short stature, defined as a height below –2 standard deviations (SD) for age, sex, and genetic background, including midparental height, is a statistical definition encompassing 2.3% of all children. It may, however, be the first presenting sign for an underlying condition. Short stature is not itself a disease, and the majority of children with short stature have a *physiologic* variant, i.e., familial short stature, constitutional delay of growth and then of puberty, or idiopathic short stature. The last category, which is also not a diagnosis, is ever-shrinking as genetic variants that affect the growth plate are identified.[109-111] Large-scale genome-wide association studies have noted that height is highly polygenic (hundreds of genes), with thousands of genetic variants distributed across the entire genome. These height-associated regions are enriched for genes in multiple metabolic pathways associated with growth.[111]

Guidelines (guidance) for the referral of a short child to a pediatric subspecialist, usually a pediatric endocrinologist, and for their detailed evaluation may vary widely by country or among regions of a country.[112,113]

The goals of the evaluation are several. The evaluation should initially differentiate variants of normal from pathological (and often treatable) causes of short stature. The former may account for 80% of referred children in many pediatric endocrine clinics.[114] Accurate height measurements following standardized procedures are essential, although children are often referred with few accurate measurements. Proper technique includes an appropriate device and a standardized protocol, but differs for infants and children. Infants are measured horizontally (recumbent length) on an examining table device with a flat board at the top and a moveable foot piece. The measurement is a two-person procedure, with one at the head being sure that it is firmly against the end, with the nose straight up. The second person applies pressure to the knees so that they are flat against the table and moves the foot piece to the soles, with the toes pointing vertically. The length is read from the scale along the table (Fig. 17.1).

A stadiometer or wall-mounted device (e.g., steel tape) is used for children 2 years of age and older. Standing height is measured with the child (shoes removed) positioned with heels, back, and shoulders against the device or wall, and the head in the Frankfurt horizontal plane with the eyes looking straight ahead. A head piece (or right-angle triangle) is then moved to the top of the head. The height of the child is read either from the scale on the device or from the steel tape (Fig. 17.1). In some cases, the head piece may have to be applied with pressure to compress the hair. This procedure should be repeated after the child steps away from the device. The two measurements can be averaged if they agree within 0.4 cm, or the process repeated if they do not. Sitting height (upper segment) is measured with a similar device, except that the child sits on the table with the head in the same plane as noted above and the head piece lowered until it reaches the top of the head. Sitting height is then read from the attached scale. Leg length (lower segment) is estimated as the difference between standing height and sitting height, and the ratio between the two (sitting height/leg length) is the upper-to-lower ratio (Fig. 17.1).

History

The history should start with the pregnancy with the child to determine if there were difficulties (including drugs the mother may have taken) that might have led to a small-for-date child. Birth weight and length are important to determine if the child was small-for-date. Other early historical notes should include feeding problems, medical diagnoses and treatments, motor and mental development, and behavioral issues in addition to height and weight records. Others in the family with a similar condition, as well as consanguinity, may offer clues for diagnosis. The heights of the parents, preferably measured, will provide an indication of the expected, sex-specific target height and range.

A child's target height is based on the sex-adjusted midparental height. It is a projected adult height (and range) based on the heights of the biological parents. The sex adjustment is important, because men are on average 13 cm (~5 inches) taller than women. The simplest way to predict the genetic potential for adult height is to add the parental heights (cm or in) and then add 13 cm for boys or subtract 13 cm for girls and then take the average. That places the other-sex parent on the same centile on the opposite sex chart. This is an estimate the genetic potential for *all* children of these parents.

For the individual child, adult height is predicted from his/her present height and bone age using, for example, the Bayley and Pinneau tables in the Greulich and Pyle atlas.[41] This may be done because bone age denotes approximately the percentage of adult height that one is at the time of the radiograph.

It should be noted that many conditions that present as short (or tall) stature do not begin at birth. As such, information that may identify a secondary growth disorder (due to nutrition, hormones, inflammatory cytokines, or extracellular fluid, as in renal tubular acidosis) should be sought. With emphasis on the growth curves for weight and height, a significant weight loss or gain, or a slowing of growth in height and when it began should be noted. Issues of relevance include growth faltering (in addition to short stature) or acceleration. Diseases of the gastrointestinal tract are often associated with both decreased weight and growth faltering, whereas several endocrine disorders may present a weight percentile greater than the height percentile (increased weight-for-height) and a growth trajectory that may be negative for height but positive for weight (as may be noted with Cushing syndrome or severe hypothyroidism). Child complaints should also be considered; for example, abdominal pain/discomfort and diarrhea may suggest inflammatory bowel disease, or severe headaches may suggest an intracranial mass. The history of medication is critical, even if certain medications have been stopped by the time the patient presents for evaluation, e.g., drugs for attention deficit disorder or glucocorticoids for inflammatory conditions. The family history may again be helpful concerning others with a similar condition and/or psychosocial, intellectual, or behavioral issues.

Physical Examination

The physical examination is likely more helpful in those with primary growth disorders (clinically defined syndromes and skeletal dysplasias caused by variants of genes associated with the growth plate), e.g., dysmorphic features, abnormal body proportions, and cardiac and other organ system abnormalities (see Fig. 17.7 for growth plate physiology). Nevertheless, most children with acquired growth faltering present a relatively normal physical examination and normal body proportions.

The degree of short stature may also offer clues to diagnosis. Children whose heights are slightly below the –2 SD cutoff are more likely to have a variant of normal growth than children with heights below –3 or –4 SD. Among more than 785 subjects with severe short stature (heights below –3 SD) after 3 years of age in the Helsinki University Hospital district, a pathologic cause for short stature, whether primary or secondary, was noted in approximately 70% of the children.[115] The conditions included various syndromes, disorders of organ systems, GH deficiency (GHD), small-for-gestational age *without* catch-up growth, and skeletal dysplasias. Normal variant, idiopathic short stature was far more prevalent at heights –3.0 to –3.5 SD than at heights more than –4.0 or –5.0 SD. More severe growth disorders (–4.0 SD and greater) were noted in children with syndromes and skeletal dysplasias (both primary growth disorders). Thus, the degree of short stature, especially at the extremes, separates the likelihood of a variant of normal short stature from the diagnosis of a pathological form.

Preliminary Laboratory Evaluation

The information in the preceding paragraphs focuses on the appropriate evaluation for children with asymptomatic short stature, i.e., those children who are short but growing at the lower end of the normal range for age. Many will have heights in the –2.0 to –3.0 SD range and a height velocity that follows along one of those trajectories. If they are truly asymptomatic after a careful history and a normal physical exam, it is overwhelmingly likely that they have a variant of normal growth and can be followed by the primary care physician or endocrinologist without laboratory evaluation, with the exception of a bone age determination. Evidence suggests a low incidence of pathology among children with asymptomatic short stature. Among 235 such patients, at most only three new pathologic diagnoses were noted; nevertheless, laboratory screening following the guidance of several Pediatric Endocrine Societies cost more than $100,000 per diagnosis.[116] The authors concluded that "… a clinician should use history, review of systems, and physical examination to guide the evaluation of individuals with short stature" [p 1050]. This information is quite helpful from several perspectives. Certain children with short stature do not require evaluation by an endocrinologist, although parents often request one. Perhaps more importantly, the history and physical examination, along with minimal laboratory testing, may lead the referring physician to a more appropriate pediatric subspecialist, for example, gastroenterologist, nephrologist, or pulmonologist.

KEY POINTS

- Is the child short?
- What is the height velocity?
- Detailed personal and family history
- Physical examination
- Bone age
- *Parsimonious* laboratory evaluation (at first)

Evaluation for Endocrine Disorders of Growth

The hallmarks of endocrine disorders of growth are greater deflections in height velocity and height standard deviation score (SDS) than in weight velocity or weight status. An upward trajectory in weight may be noted as height SDS is declining. The most prevalent endocrine system–related conditions include hypothyroidism, Cushing syndrome, and GHD, and perhaps GH insensitivity. If poor nutrition, either malabsorption or insufficient intake, is prominent as in celiac disease, inflammatory bowel disease, or chronic caloric deficit, the loss of weight is generally in excess of that in height. Hypothyroidism and Cushing syndrome are described in specific chapters. The current discussion focuses on disorders of the GH/IGF-1 axis.

Growth Hormone/Insulin Growth Factor-1 Axis

The GH/IGF-1 system is the main regulator of postnatal human growth (Figs. 17.8 and 17.9). It regulates this complex process by integrating

genetic and nutritional factors, along with signals from thyroid hormone, insulin, and glucocorticoids. Psychosocial aspects may also be important.[117]

Human GH is a heterogeneous protein with several molecular isoforms. This heterogeneity is expressed at the level of the *GH* gene, mRNA splicing, posttranslational processing, and GH metabolism, and poses a challenge to complete understanding of GH bioactivity, accurate measurement, and assay standardization.[118,119] Two *GH* genes, *GH1* and *GH2*, are on the long arm of chromosome 17q23.3: the former encodes the predominant isoform, 22 kDa (191 amino acids), which contains two intramolecular disulfide bonds.

Growth Hormone Release and Action

The release of GH from the anterior pituitary is mediated by two peptides secreted by the hypothalamus, GH-releasing hormone (GHRH) and the inhibitory hormone somatostatin (somatotropin release–inhibiting hormone [SRIH]) (Fig 17.8). A pulse of GH is generated by the simultaneous rise in GHRH and decline in SRIH. The amount of GHRH released likely determines the amplitude of the GH peak, and the frequency and duration of the GH secretory event is primarily under SRIH control. The pulse is also stimulated by ghrelin, which is produced mainly in the stomach, but also in the hypothalamus. IGF-1 and GH itself exert negative-feedback control at the hypothalamus. GH is transported in the serum by binding proteins: the major one, GHBP, is identical to the receptor.[118]

GH acts by binding to the GH receptor (GHR), which is expressed in most tissues. The GHR is a transmembrane receptor belonging to the class 1 cytokine receptor family. Once this binding takes place, the GHR undergoes conformational changes that result in activation of Janus kinases (JAK2), followed by recruitment and phosphorylation of signal transducers and activators of transcription (STATs) that, among other actions, induce the synthesis of IGF-1, IGFBP3, and the acid-labile subunit (ALS) encoded by the IGFALS gene (Fig. 17.9).[120] This ternary complex circulates assembled as a 150-kDa protein, then IGF-1 (a 7.6-kDa protein, 70 amino acids), whose gene is located at chromosome 12q23, is liberated so it may bind with its receptor (IGF-IR) to promote growth. Circulating IGF-1, stimulated by GH action on the liver, is the main mediator of generalized GH actions; however, it is not the only route through which GH can exert its effects, for example, at the growth plate.[121,122] IGF-1 levels are age- and sex-dependent. Serum levels are high in the fetus, but drop shortly after birth and then increase slowly until late prepuberty or very early puberty. The levels subsequently increase approximately 3-fold, concomitant with the rise in the quantity of GH secreted, peaking near the time of PHV.[123] Peak values occur earlier in girls as their pubertal maturation increases.

Once free IGF-1 binds to its receptor, signaling cascades are triggered intracellularly, with two essential ones being the mitogen-activated protein kinase (MAPK) and the phosphatidylinositol 3-kinase (PI3K) cascades. The MAPK cascade is primarily responsible for the proliferation of muscle cells, and the PI3K cascade for cell differentiation.

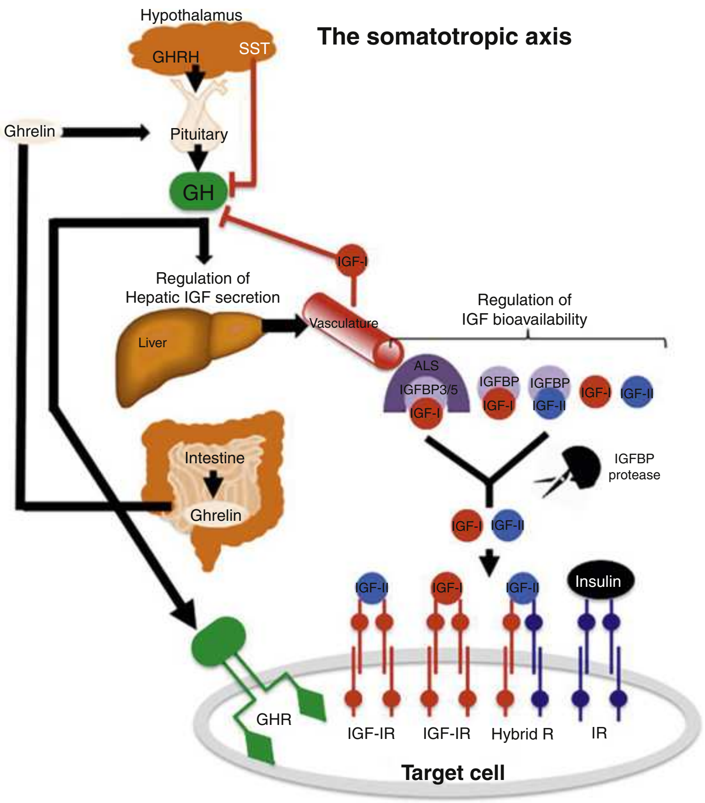

Fig. 17.9 **The Somatotropic Axis.** Hypothalamic growth hormone (GH)-releasing hormone and somatostatin, as well as intestine-secreted ghrelin, regulate pituitary secretion of GH. Once released to the circulation, GH stimulates liver production of insulin growth factors (IGFs) and a few of the IGF binding proteins (IGFBPs). In the vasculature, IGFs are found in binary and ternary complexes, which increase their half-lives. Serum and tissue proteases act upon the IGFBPs to liberate IGFs and increase their bioavailability. Target cells expressing the IGF-IR, insulin receptor, or hybrid receptors bind the IGFs and initiate phosphorylation cascades to enhance cellular proliferation, differentiation, and function. GH receptor is found on almost all cells. Upon binding to its receptor, GH initiates signaling cascades to promote cellular function that may be IGF-dependent or -independent. (Yakar, S, Werner H, Rosen CJ. Insulin-like growth factors: actions on the skeleton. *J Mol Endocrinol.* 2018;61:T115–T137.)

GH and IGF-1 (and other growth factors) work in concert to promote cartilage and bone growth. GH has a dual effect on the growth of epiphyseal cartilage and differentiation of cartilage cells, as well as the generation of IGF-1. The proximal zone of cartilage, which is close to the bony segment of the epiphysis, consists of a narrow band of germinal or stem cell chondrocytes. GH preferentially stimulates differentiation of these prechondrocytes, while IGF-1 stimulates the clonal expansion of the more differentiated cells in the distal proliferative zone. GH, but not IGF-1, stimulates lipolysis.

GHD may be congenital or acquired. It may also be isolated or in combination with other anterior hormone deficiencies (multiple pituitary hormone deficiencies [MPHD]) and dysmorphic findings or with involvement of other organ systems (see also Chapter 18). Children with congenital severe GHD have only a slightly reduced birth length and may not immediately show growth failure, which becomes prominent in the second half of the first year. The children also show a higher frequency of breech presentation and perinatal asphyxia. Neonatal morbidity may include hypoglycemia and prolonged jaundice. When GHD is combined with deficiency of adrenocorticotropic hormone (ACTH), hypoglycemia may be severe. The combination of GHD with gonadotropin deficiency can cause microphallus, cryptorchidism, and hypoplasia of the scrotum.

Children with acquired GHD present with severe growth failure, delayed bone age, and increased weight:height ratios. Causes of acquired GHD include intracranial tumors involving the hypothalamic-pituitary region (e.g., craniopharyngioma), cranial irradiation, and head trauma (Table 17.4).

Another cause of hypopituitarism in children more than 2 years of age is psychosocial short stature, also known as deprivational short stature. Children exposed to a severely traumatic home environment are characterized by bizarre behaviors including gorging and vomiting (hyperphagia); sleep disturbance, night wandering often in search of food; pain agnosia; abnormal and disturbed relationship with primary caregiver; temper tantrums; and poor peer relationships. Objectively, the children have subnormal height velocity, but often an appropriate weight for height.

Catch-up growth may be marked with removal from the disturbed environment, as may be amelioration of many of the signs and symptoms noted previously. The relationship to the GH/IGF-1 axis is that, if tested early after removal from the environment, whether measured by the spontaneous release of GH or by the GH response to a pharmacologic stimulus, the children respond as if GH-deficient. Within a few days, responses to these tests generally revert to normal. Growth rates become remarkably high within weeks following removal from the home environment, even during hospitalization. Given this high rate of growth following an extended period of subnormal growth and the reversion of the testing to normal, this condition may be considered a form of *reversible* hypopituitarism, at least for the GH/IGF-1 axis, and often for the corticotropin-releasing hormone/ACTH/adrenal axis.[117]

TABLE 17.4 Genetic Disorders of Growth Hormone (GH)

Gene	Phenotype	Inheritance	OMIM #
Isolated GH deficiency			
GH1	Isolated GH deficiency	AR, AD	139250, 612781, 173100, 262400
GHRHR	Isolated GH deficiency	AR	139197
Combined pituitary hormone deficiency			
POU1F1	GH, TSH, prolactin deficiencies	AR, AD	173110
PROP1	GH, TSH, LH, FSH, prolactin and evolving ACTH deficiencies	AR	262600
Specific syndromes			
HESX1	Septooptic dysplasia	AR, AD	182230
LHX3	GH, TSH, LH, FSH, prolactin deficiencies; limited neck rotation	AR	600577
LHX4	GH, TSH, ACTH deficiencies with cerebellar abnormalities	AD	262700
SOX3	Hypopituitarism and mental retardation	X-linked	312000
GLI2	Holoprosencephaly and multiple midline defects	AD	610829
SOX2	Anophthalmia, hypopituitarism, esophageal atresia	AD	206900
GLI3	Pallister–Hall syndrome	AD	146510
PITX2	Rieger syndrome	AD	180500

AD, autosomal dominant; *AR*, autosomal recessive; *TSH*, thyroid-stimulating hormone; *LH*, luteinizing hormone; *FSH*, follicle-stimulating hormone; *ACTH*, adrenocorticotropic hormone.

A number of conditions (syndromes) that involve linear growth and body composition have become of interest to internists because the children/adolescents who present with them survive into young adulthood. The largest group is likely the survivors of childhood cancer, many of whom have endocrine system–related morbidities, especially those related to growth and puberty.[124-126]

New to many internists are those adolescents with Prader–Willi syndrome or cystic fibrosis. Prader–Willi syndrome (OMIM 176270) is a multisystem, genetically heterogeneous condition caused by a lack of paternal gene expression in the chromosome 15q11-q13 PWS locus. Although the clinical phenotype may change over time, many adolescents and emerging adults have had the benefit of GH therapy, with increased adult height and a more normal body composition, indicated by an increased lean body mass and decreasing fat mass; although both remain abnormal in most subjects. The most common metabolic issue, in addition to hypogonadism, either secondary or mixed primary and secondary, is insulin resistance and disordered glucose metabolism. This often occurs in concert with the unresolved issue of adult treatment with recombinant human GH (rhGH), with effects on body composition and the regional distribution of body fat, as well as quality of life.[127]

Three and four decades ago it was uncommon for children and adolescents with the usual mutation causing cystic fibrosis to survive to emerging adulthood; many now survive into their fourth and fifth decades. Nutritional support is the cornerstone for metabolic function, but virtually half have a “new variety” of diabetes mellitus or cystic fibrosis–related diabetes, whose treatment is radically different from that for either type 1 or type 2 diabetes mellitus. The key deficiency is insulin itself and its strong anabolic action in muscle tissue. As this disease complication unfold during adolescence, there is a diminution of the anabolic action on muscle, and often a worsening of the pulmonary disease.[128] Patients with these and similar conditions now require an endocrinologist for part of their ongoing medical and psychological care.

Diagnostic Approach

GHD should be considered in the context of auxology, i.e., growth faltering and usually an increased weight:height ratio, but it is *confirmed* by biochemical and stimulation testing. The first step is to evaluate for other potential causes of growth failure, including chronic systemic disease, e.g., hypothyroidism, Turner syndrome (in girls), and skeletal disorders. This is accomplished through a thorough medical history, physical examination, and bone age determination. Additional laboratory evaluation should be performed when appropriate, including screens for systemic disease, undernutrition, inflammation, and thyroid function, and a karyotype in girls to rule out Turner syndrome. GHD is effectively excluded in children with normal height velocity and bone age.

Specific to GHD, in addition to the bone age radiograph obtained for most evaluations of short stature, an IGF-1 level should be measured; in children below age 3 years, an IGFBP-3 level should be measured. Although individual values will not permit the specific diagnosis of GHD, children with levels above 0 SDS for age and sex may be excluded. These findings are generally sufficient to exclude GHD without stimulation tests (see later).

When GHD is congenital and near-complete, the diagnosis is straightforward, as affected children present with severe growth failure, delayed bone age, and very low serum concentrations of GH, IGF-1, and IGFBP-3. For patients with these clinical characteristics, it is reasonable to make the diagnosis of GHD without performing GH stimulation testing (see later). Lesser degrees of growth faltering and decreased IGF-1 and IGFBP-3 levels are consistent with GHD, but are also consistent with a number of other causes of growth failure, including poor nutrition. If not explicable on the basis of undernutrition, low IGF-1 and/or IGFBP-3 levels are strongly suggestive of a diagnosis of GHD, but this must be confirmed by provocative GH testing (see later). MRI of the hypothalamo-pituitary region (with and without contrast) is recommended for children with suspected GHD and may be specifically useful in infants, where it is more likely that structural abnormalities will be found.[129]

A significant minority of children (3%–30%, depending on the study) have an affected parent or sibling, while several genetic causes, for example, transcription factor mutations or mutations of GH itself, the GHRH receptor $G_{s\alpha}$ or the GH secretagogue receptor, have been described in detail.[130,131]

Growth Hormone Stimulation Tests

Indications. Provocative (stimulation) GH testing is indicated for most patients to confirm a diagnosis of GHD. Because these tests have limitations, the results should not be used as the sole diagnostic criterion and should be interpreted in the context of auxologic findings, bone age, and IGF-1 and IGFBP-3 concentrations.[113] Provocative testing is *not* necessary for patients in whom other clinical criteria are sufficient to make the diagnosis of GHD:

- Pituitary abnormality (secondary to a congenital anomaly, tumor, or irradiation) and a known deficiency of at least one other pituitary hormone, in addition to auxologic criteria.[113,132]
- Newborn with a congenital pituitary abnormality (ectopic posterior pituitary and pituitary hypoplasia with abnormal stalk) or known deficiency of a pituitary hormone, along with hypoglycemia, at which time a simultaneous serum GH concentration is less than 5 mcg/L.[132]
- Infant or young child with extreme short stature (height <–3 SD), normal nutrition, significantly reduced IGF-1 (<–2 SD) and IGFBP-3, and delayed bone age. This is the classic presentation of congenital and severe GHD, including MPHD; most experts agree that provocative testing is not required to make the diagnosis.

Limitations of Growth Hormone Stimulation Tests

- Tests are pharmacologic and may not indicate the underlying physiology.
- Reproducibility in both normal and GHD patients is poor, even with the same tests done on different days.
- Age and sex steroid hormone status affect results, and use of sex-steroid "priming" does not have a consensus.
- Nutritional adequacy and body composition, particularly adipose tissue, can affect results.
- GH assays vary, with large interassay variance.
- All are expensive.

Growth Hormone Treatment (See Also Chapter 18)

The effects of GH treatment for GHD differ markedly depending upon the life phase of the individual. For infants and children, it is used mainly to increase linear growth, although in the former it may be important to prevent hypoglycemia as well. Relatively higher doses are necessary than those required in adults for promotion of lean body mass, lipolysis, and salutary effects on quality of life. The preceding pertains only to GHD, for children who receive GH therapy for any of the other seven FDA-approved indications will not require GH therapy as adults. Only a minority of those treated for GHD as children will require GH as adults, making it mandatory (with some exceptions) that stimulation testing be done at the transition of adolescent patients to emerging adulthood.

A special case may be made for those who receive cranial radiation therapy for central nervous system tumors. The "dose-response" curves for GHD depend on the type, photon or particle, with the latter having a sharper focus and causing less collateral destruction, as well as differences in how fractionated the radiation is. The particle-based therapies are often given just once. The dose should be related to that delivered to the hypothalamus/pituitary and not to the targeted tumor. Early on it is the hypothalamic area that is most sensitive, but later the pituitary itself must be considered. Generally speaking, a dose of less than 18 Gy does not cause hypopituitarism, but doses between 18 and 24 Gy increasingly are found in irradiated children. Importantly, those children who receive more than 18 Gy of radiation to the hypothalamus should be followed lifelong, at first for growth and then for the adult consequences of GHD.[126,133]

Although not completely agreed upon, there does not appear to be an increase in the recurrence rates for central nervous system tumors following irradiation, whether treated with rhGH or not. In a similar manner, the more recent studies note virtually no differences in secondary neoplasms (mainly meningiomas) following irradiation therapy based on treatment or not with rhGH.[133,134]

Most centers wait 1 year after the end of therapy to begin GH treatment, although the scientific basis for this practice is limited. For a "benign" tumor, craniopharyngioma, there seems little reason to wait that long if it is obvious that the child/adolescent is GH-deficient.

Dosing and Monitoring of Growth Hormone Therapy

The typical range of starting doses of rhGH is between 20 and 35 micrograms/kg/day, administered subcutaneously once daily (0.16–0.24 mg/kg/week); the lower end of the range is used for patients with severe GHD. Treatment should be started as early as possible to achieve the greatest growth response. This is likely to change soon, as multiple formulations of longer-acting GH are in phase 3 trials in children.

Monitoring is usually accomplished by measuring height and estimating height velocity and IGF-1 at 3- to 4-monthly intervals. After 6 to 12 months, more credence is given to the height velocity than the IGF-1 level, as some children will show catch-up growth even at relatively low IGF-1 SDS. The IGF-1 level serves as a safety marker, as one tries to keep it within +0.5 to +1.5 SDS for age and sex (stage of maturation during puberty). One may also use the IGF-1 level at 1 month for both a safety (too high) and efficacy (above 0 SDS) marker and increase or decrease the dose before the 3-month visit. The latter provides the physician an additional opportunity to evaluate how the patient and parents are reacting to the new medication.

GH therapy is generally continued until linear growth decreases to less than 1.5 to 2.0 cm/year. However, this is an individualized decision, and in some adolescents it may be appropriate to terminate therapy sooner. Patients should be retested (see later) for GHD using GH stimulation tests to determine if they remain GH-deficient. Treatment may then be continued for metabolic indications, i.e., to maintain healthy body composition, lipid profiles, and bone mass.

The more common adverse effects of rhGH therapy include unmet patient and parental expectations, idiopathic intracranial hypertension (especially in the first months), slipped capital femoral epiphysis, and worsening scoliosis (because of more rapid growth). Growth-inhibiting antibody production is exceedingly rare with the recombinant products. Longer-term risks, including new and recurring benign and malignant conditions, have recently been described in detail.[135]

In patients in whom rhGH treatment is not begun until adolescence, the patient may not acquire the desired height with GH therapy alone, as there already may be significant partial closure of the growth plates. To delay further epiphyseal maturation, adjunctive treatment with a gonadotropin-releasing hormone agonist or an aromatase inhibitor has been explored. These are not generally recommended, because their safety and efficacy have not been established.

Retesting for Growth Hormone Deficiency During the Transition to Emerging Adulthood

During the transition from adolescence to emerging and young adulthood after linear growth has essentially ceased, growth in bone mass and lean tissue mass (composition) continues and reflects the metabolic actions of GH. GH is a necessary element, in addition to quality of life.[136] Some adolescents will require retesting. Those with congenital, isolated GHD require retesting, because more than two thirds will have normal provocative tests near the end of the growth period. In those with genetic, organic, or structural causes of GHD, the deficiency is permanent in the vast majority. Individuals whose GHD is due to radiation therapy should be followed for a longer period of time, because the effect of radiation on the GH axis may not be manifest for 10 years.

How should the retesting be done? The first step is to measure an IGF-1 level after 4 weeks without receiving rhGH at the time of a significant decrement in height velocity, e.g., 2.0 cm/year. A normal test indicates sufficient GH, and these patients do not require additional testing or GH therapy. If the IGF-1 level is below –2 SD, one may proceed to stimulation testing. However, there are certain conditions for which retesting is not necessary. These include patients with three or more other anterior pituitary deficiencies, those with genetic causes of GHD, and those with structural causes of GHD. Although a plethora of tests have been described, insulin-induced hypoglycemia and glucagon are the most common. The cutoff values for the adult differ from those of children and adolescents, and are lower depending on the stimulus and laboratory normal range.

Macimorelin, which has high reproducibility, sensitivity, and specificity, is the newest FDA-approved agent for adults.[137] It is currently in clinical trials for patients aged less than 18 years. Patients remaining GH-deficient will require continued rhGH therapy, although the dose is very much smaller, varying from approximately 0.3 mg/day to 1.0 mg/day, with the higher doses for women. There is no consensus on how to gradually decrease the high doses for the promotion of growth in these adolescents (in the range of 1.5–3.5 mg/day) to the much smaller doses noted above for the adult. Common practice is to do so slowly over 1 to 2 years. The dose is often higher in girls, especially those taking oral estrogens. Rather than monitoring height velocity, one may monitor IGF-1 levels and perhaps perform an occasional dual-energy x-ray absorptiometry (DXA) scan for body composition and bone mineral density. Adequate therapy is indicated by an IGF-1 level between 0 and 1 SD and the absence of symptoms referable to GHD in the adult.

Retesting for GHD in late adolescence is limited to those who have GHD *per se*; the other seven indications for children are concerned with height velocity and near-adult height, but do not carry over to the adult. However, some recent studies point to an adult indication for those with the Prader–Willi syndrome; but it is indicated for its effects on body composition and quality of life.[138,139]

KEY POINTS

- Growth hormone (GH)/insulin growth factor (IGF)-1 axis
  - GH deficiency
  - GH insensitivity
- **Diagnostic approach**
  - Auxology
  - Skeletal age
  - IGF-1 level
  - GH stimulation tests
  - GH treatment and monitoring
    - Height velocity
    - Change in bone age

EVALUATION OF CHILDREN WITH TALL STATURE

Similar to the evaluation of children with short stature and growth faltering, a systematic diagnostic approach for children with tall stature or accelerated growth should be in place. Tall stature is indicated by height above +2 SD for children of the same age and sex, or above +2 SD for midparent height, while accelerated growth should be diagnosed or excluded in the context of primary (syndromic) or secondary growth disorders, e.g., excessive GH or premature secretion of sex steroid hormones. As with many children evaluated for short stature, those with tall stature are likely to have a variant of normal growth or constitutional tall stature, and to have tall parents.

The rationale and diagnostic approach to tall stature have been recently reviewed.[140] These conditions are considerably less common than those with short stature in most pediatric endocrine clinics. Nevertheless, several common syndromes present with tall stature and accelerated growth. The first includes several X and Y (sex) chromosome aneuploidies (SCAs); the most prevalent are Klinefelter syndrome (47,XXY) and 47,XXX, while the less common are 47,XYY and 48,XXYY. The genotypes are rarely diagnosed before puberty, except for increasingly routine prenatal diagnosis based on multiple types of genetic diagnoses, for example, array analysis, karyotype, and whole-exome sequence analysis, or diagnosis because of behavioral and learning phenotypes in these children. The hypothalamo-pituitary gonadal axis differs among those with SCAs:

- Males with a 47,XXY karyotype are tall with eunuchoid body proportions. They have hypergonadotropic hypogonadism and small, often firm, testes.
- Males with a 47,XYY karyotype have normal size testes and generally normal hypothalamic–pituitary–gonadal (HPG) axis hormones, i.e., slightly below-average luteinizing hormone (LH), testosterone, and inhibin B concentrations, and slightly above-average follicle-stimulating hormone (FSH) and antimullerian hormone concentrations.
- Girls with 47,XXX are tall and hypotonic. They have a mainly normal HPG axis, i.e., sexual maturation occurs largely within the physiologic range. However, psychological features including an increased prevalence of attention deficit, and mood disorders may be prominent at evaluation.
- Males with the very much less common 48,XXYY karyotype are tall with eunuchoid body proportions. They have hypergonadotropic hypogonadism (although often to a lesser degree than those with the 47,XXY karyotype), gynecomastia, small testes with germinal aplasia, and tubular hypoplasia.

A second common overgrowth syndrome is Marfan syndrome (OMIM 154700), for which a systemic clinical scoring system has been devised, followed by sequence analysis of the *FBN1* gene or of a panel of connective tissue disorders that includes the *FBN1* gene.[140] Thus, the sequence of evaluation includes diagnostic clues from personal and family histories of the patient; physical examination for dysmorphology and body proportions (height and sitting height), and of the genitalia; and evaluation of height growth curves for accelerated growth. Together, these analyses should permit a directed laboratory investigation.[140]

There are several other causes of syndromic tall stature, and use of genetic tests is increasingly more prominent in the diagnosis of these relatively rare and perhaps atypical conditions in which dysmorphic findings and comorbidities are consistent findings.[141]

KEY POINTS

- Is the child tall?
- What is the height velocity?
- Detailed personal and family history
- Physical examination
- Bone age
- *Parsimonious* laboratory evaluation (at first)

ENDOCRINE CAUSES OF TALL STATURE

Endocrine causes of tall stature include central precocious puberty and peripheral sexual precocity, mainly non–salt-losing congenital adrenal hyperplasia. (The salt-losing variety either leads to early diagnosis and treatment, or neonatal death in adrenal crisis.)

Constitutional activation of the LH receptor, which is also called "testotoxicosis," is less common. It is also uncommon for hyperthyroidism to cause significantly accelerated growth and tall stature, because the signs and symptoms of the disease are usually noted early, and treatment is well described. "Catch-down growth," that is, below the normal rate, is often noted with effective treatment of the hyperthyroidism.

Less commonly, a child (or family) with familial glucocorticoid deficiency or familial glucocorticoid resistance will present to a clinic; with this condition, ACTH drives adrenal androgen secretion and peripheral sexual precocity. Appropriate treatment with glucocorticoids slows the height velocity and diminishes genital and bone age advancement more in the former than in the latter.[142]

The McCune–Albright syndrome consists of polyosteotic fibrous dysplasia, precocious (and occasionally) peripheral sexual precocity, and café-au-lait skin pigmentation leading to tall stature in boys and girls, but is more common in girls. GH excess is considerably less common, but can occur along with other uncommon associated endocrinopathies: hyperthyroidism, Cushing disease, FGF23-mediated phosphate wasting, and hypercortisolism.[143]

Because estrogens accelerate epiphyseal closure, youth with syndromes of diminished estrogen synthesis (aromatase deficiency) or estrogen action (estrogen receptor α deficiency) will continue to grow well beyond adolescence. Both also have eunuchoid proportions and osteoporotic bones. However, those with the estrogen receptor α deficiency will have absent breast development despite elevated levels of estradiol and do not respond to exogenous estradiol with breast development. Those with aromatase deficiency will have virtually no circulating estradiol, but will respond to exogenous estradiol with breast development and closure of the epiphyses of the long bones.

GH excess causes both gigantism and acromegaly as the long bone epiphyses close. Its diagnosis is based on accelerated growth, acral enlargement, and a pituitary mass as noted on cranial MRI scan. It may often be due to a germline mutation (see Chapter 18). Very rarely, especially in children, accelerated growth and acral changes may be due to the ectopic secretion of GHRH. Treatment for the rare child with this condition differs little from that for adults—transsphenoidal tumor removal (if possible) and either somatostatin analogs, GH receptor antagonists, or radiation therapy.

KEY POINTS

- Growth hormone excess
- Precocious puberty
- McCune–Albright syndrome
- Congenital adrenal hyperplasia (inadequately treated)
- "Testotoxicosis"
- Familial glucocorticoid resistance

Treatment of Children/Adolescents With Tall Stature

Individuals with the constitutional (familial) tall stature do not ordinarily require treatment, as they do not have a pathological condition. Nevertheless, decades ago a number of constitutionally tall girls were treated with high doses of estrogens, perhaps 5-fold the normal replacement dose for a woman, to accelerate epiphyseal closure and diminish adult height. This likely led to diminished adult height, only if started in proximity to the initiation of pubertal maturation. However, this treatment led to rapid pubertal maturation out of synchrony with age peers. Of more clinical relevance, the treatment was associated with highly significant clinical signs—increased thromboembolic events, perhaps a heightened risk of breast cancer, and late negative effects on fertility.[144]

Some males with tall stature were treated with high-dose testosterone administration. The treatment was associated with rapid pubertal maturation, often aggressive behavior, frequent and occasionally painful erections, and very severe acne.

Growth Evaluation of Children With Obesity

Many syndromes and medical conditions associated with obesity are linked to growth disorders and may lead to short stature (majority), and occasionally tall stature. The subsequent emphasis is on obese children without syndromes and medications such as glucocorticoids that lead to both obesity and growth faltering.

The prevalence of obesity in children, adolescents, and adults is ever increasing, but methods for quantifying it have been relatively stable. Obesity, especially severe obesity, affects linear growth and pubertal maturation in youth and cardiometabolic risk in adults.

More specifically, the trends for the BMI indicate a small change at the medians (50th centile), but a major upward change especially above the 85th (overweight) and 95th centiles.[145] Plotted data aggregate between the 95th and 99th+ centiles, but it is difficult to evaluate the trajectory of the weight gain or the response to therapy for these obese subjects. Absolute values change during adolescence, and perhaps a more useful way to present the data is to use the BMI SDS. A single 99th percentile represents a large range of BMI values with a practical upper limit of $Z = +4.0$. However, at the very highest levels, the BMI SDS is weakly associated with other measures of body fatness and comorbidities.[146] These authors recommend that the BMI should be expressed relative to the US Centers for Disease Control and Prevention 95th centile (% BMI_{p95} scale), especially in trials that evaluate interventions.[147] This permits tracking of low- and normal-weight children in addition to those with extreme obesity (Fig. 17.10).

Investigators have used other constructs to aid the graphical presentation of the data. Although not used widely, the triponderal mass index (TMI; weight [kg]/height^3 [m^3]), in contrast to the BMI, shows greater stability during adolescence, so that it may be used as an absolute number rather than as a calculated score.[148] Moreover, the TMI provides a better estimate of body fat compared with DXA estimates and leads to a reduced misclassification of adolescents as overweight when they are of normal weight.

A large epidemiologic study in Korea with almost 10,000 subjects aged 10 to 20 years noted that virtually all factors *associated* with the metabolic syndrome (diastolic blood pressure, excepted) were more likely to be abnormal in those TMI scores in the overweight than in those within the normal range within the same BMI classification. Thus, tracking the TMI z-score may indicate which emerging and young adults should be more closely surveyed for impending cardiometabolic dysfunction.[149]

An additional comorbidity is apparently early (not necessarily precocious) puberty, with some growth and maturational consequences. In a longitudinal study of 9- and 10-year-old girls at baseline,[150] mean age at menarche was earlier in Black (11.7 years) than in White (12.0 years) participants, indicating a significant ethnic/racial gradient. A consequence was that early-maturing girls in both ethnic groups were taller and had a greater (often earlier) PHV than the later-maturing girls; however, at near-adult height, the later-maturing girls were more than 2 cm taller. The latter is a relatively small difference within the normal range, but highly significant given the large sample studied. The differences are likely attributable to estrogens, given the earlier thelarche and menarche and more rapid epiphyseal closure that led to the shorter stature.

Perhaps the easiest to visualize are charts derived from values above the 95th percentile for weight. It does not have an upper bound, and

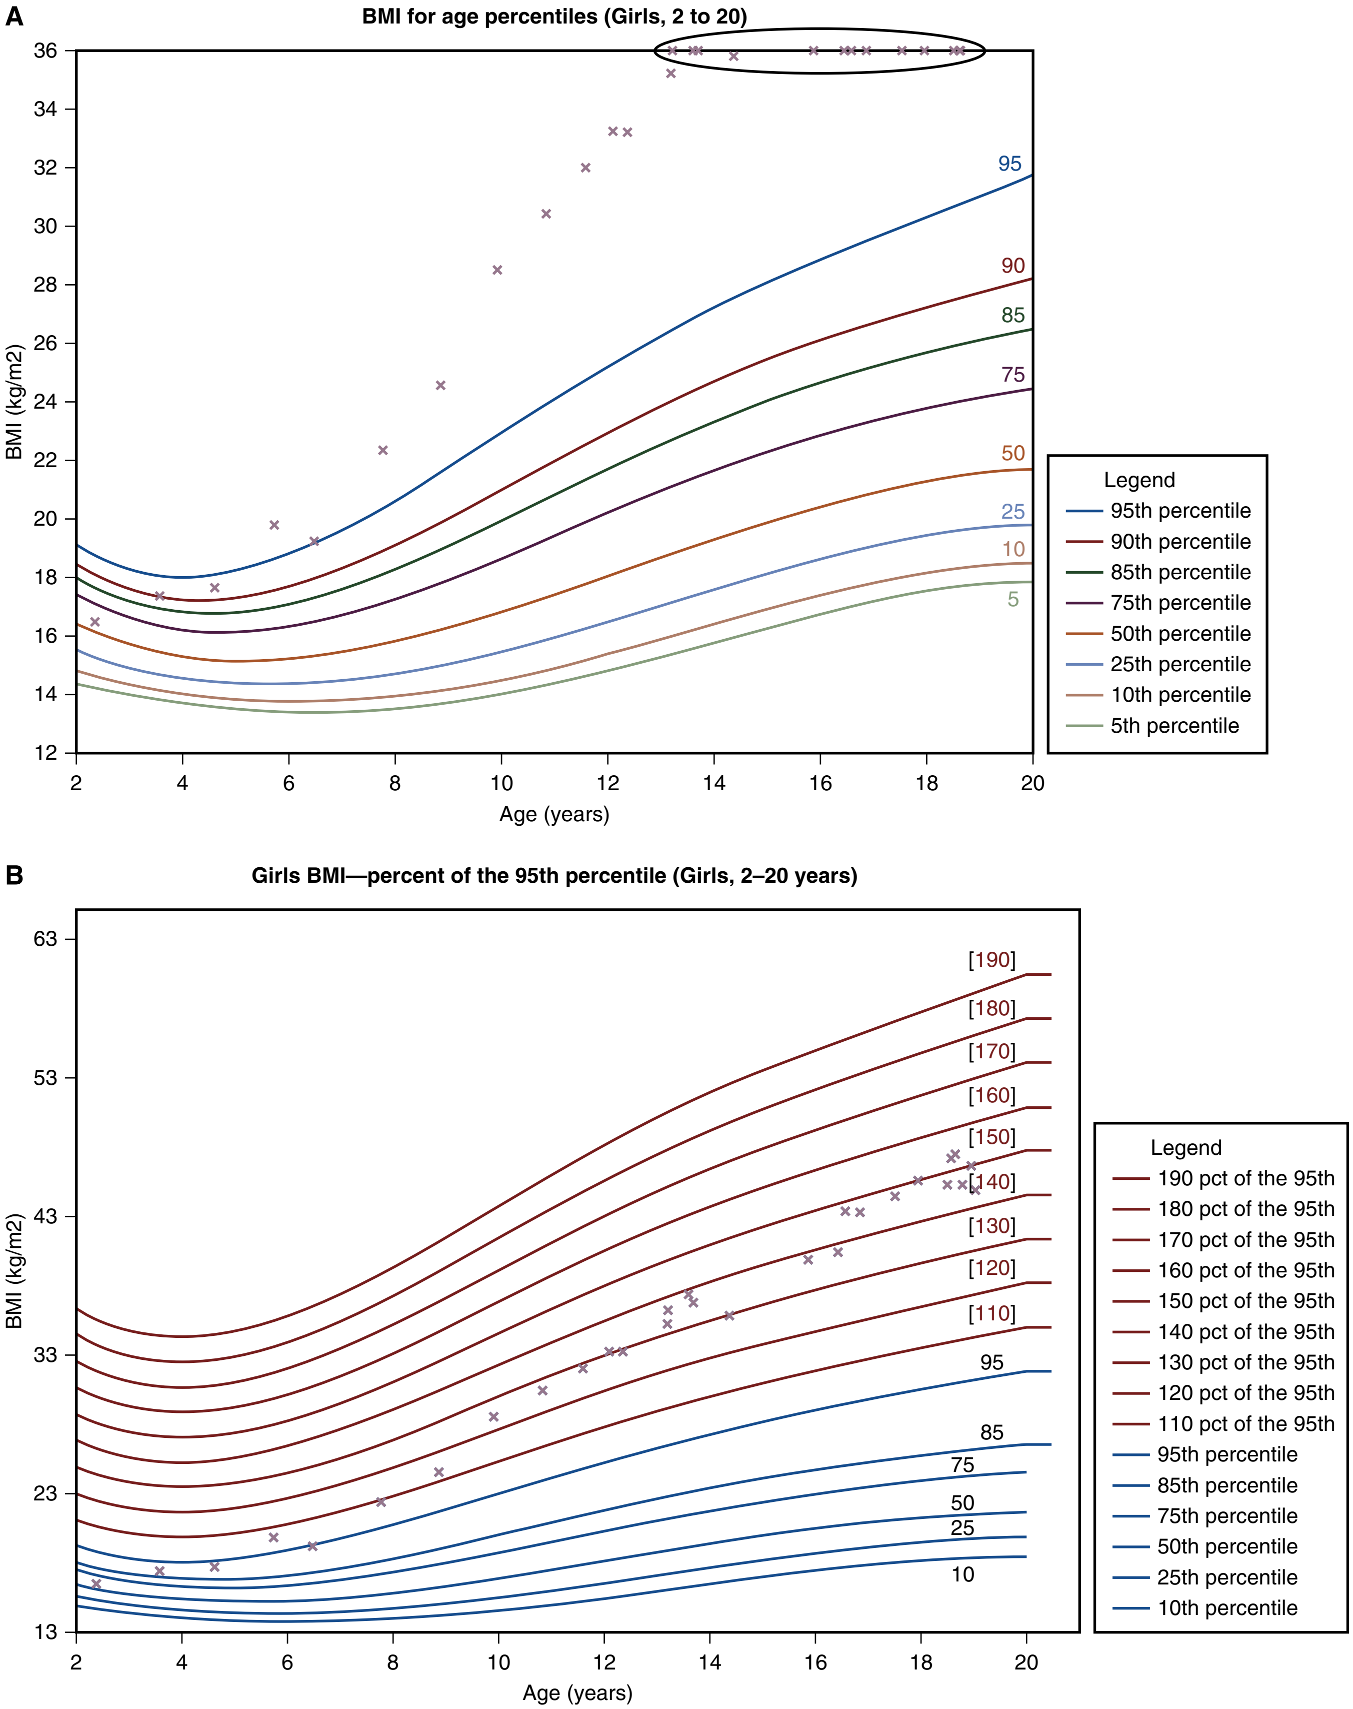

Fig. 17.10 **Clinical tracking of severely obese children. A,** US Centers for Disease Control and Prevention body mass index (BMI) (2000) growth chart, girls aged 2–20 years, percentiles. **B,** Obesity BMI growth chart, girls aged 2–20 years, percent of 95th percentile. *From Centers for Disease Control and Prevention (CDC)*

one can track trajectories over time, especially the effects of therapy. In concept, these differ little from some of the height charts for very short children that show –3 SD to at least –5 SD. All of the very short children are "far below" the –2 SD trajectory, but one can more easily denote response to therapy, e.g., in children with achondroplasia receiving one of the C-type natriuretic peptide analogs.[151]

In general, children with obesity are relatively tall for age, although their weight is in excess for height, leading to the increase in BMI above the 95th centile. Bone age determinations are often advanced, and the children may enter puberty earlier than children of the same age who are of average weight. The temporary increase in height gain in childhood may be compensated by subsequent subnormal height gain during adolescence, and in turn shorter adult stature.

In addition, those with the more severe forms of obesity are at greater risk for multiple cardiometabolic dysfunction, as noted for low high-density lipoprotein cholesterol levels, elevated systolic and diastolic blood pressure, and high triglyceride and glycated hemoglobin levels.[152,153] Although the relative risk is high, the absolute risk of cardiometabolic disease is low in the adolescent; however, these are the emerging and young adults who should be followed prospectively.

The trajectory of BMI throughout childhood and adolescence may also be predictive of risk of cardiometabolic dysfunction in adulthood. In a three-decade longitudinal study of Chinese children beginning at age 6 to 18 years, the high BMI (high trajectory) increasing group (~39%) had relative risk ratios above 3.0 for hypertension, type 2 diabetes, and low density lipoprotein–cholesterol concentration compared with the low BMI (low trajectory) increasing group. From these results one could derive preventive strategies, although caution is warranted. The dataset did not include younger children, especially the time of adiposity rebound, and the region of China in which the study was set had a high salt intake.[154]

KEY POINTS

- Continued weight gain with slowing height velocity is characteristic of children with endocrine causes of obesity: hypothyroidism, growth hormone deficiency, Cushing syndrome, and pseudohypoparathyroidism. On the other hand, high normal height velocity in the presence of excess weight gain is characteristic of the vast majority of children and adolescents with exogenous obesity.

CONCLUSIONS

Growth is a continuous process during childhood and adolescence. Its quantitation permits the clinician and investigator to note whether it is within or outside the broad range of normal variability. Growth disorders are heavily weighted toward individuals with various deficiencies or insufficiencies leading to short stature and falling further behind their peers.

We have discussed the methods of measuring and analyzing growth and maturation with emphasis on skeletal (bone) age; both set the stage for diagnosis, laboratory, and imaging determinations, as well as treatment considerations. Some of the variability in determining SA will diminish as automated radiograph analyses become more available and standardized, and perhaps in using nonradiation methods, such as ultrasound techniques.

The clinical section emphasizes disorders of the GH/IGF-1 axis, although there are likely many more that affect the growth plate directly, and the diagnoses of these will be materially aided by more modern genetic techniques that should become available in commercial laboratories with relatively low cost and quick turn-around time.

Obesity has become a major nutritional problem, especially over the past generation. More consideration is being given to the definition and responses to therapies as new charts are introduced to follow the effects of interventions on the weight trajectory. Most children and adolescents with nonsyndromic obesity are growing at the upper limits of normal with mildly advanced SA, and thus are often relatively tall as children but of more average height as late adolescents, because pubertal maturation is advanced as well.

INTRODUCTION

The height of an individual is the culmination of a complex process that results from an interaction between genes, nutritional status, hormonal milieu, and environmental factors.[1] In terms of adult height, fetal growth is critical and has major implications for the ultimate stature of an individual. Birth length is approximately 30% of final height, and with a crown-rump length velocity of 50 to 60 cm/year; this period represents the fastest rate of growth achieved by an individual.[2] This growth is mediated by maternal nutrition and a number of growth factors such as insulin-like growth factor (IGF)-1, IGF2, fibroblast growth factor, epidermal growth factor, transforming growth factors α and β, and insulin. Any compromise in maternal nutrition or in the production of these growth factors is associated with intrauterine growth restriction.

Over the first 2 years, a period of "catch-up" or "catch-down" growth commonly occurs while the infant establishes his/her own growth trajectory, with a marked increase in the correlation between current height and final height ($r = 0.8$) by 3 years of age. As a result, growth along a predictable channel is the hallmark of the healthy child.

Postnatal growth is best described by the infancy-childhood-pubertal model of growth.[1] These three phases are regulated by different components of the endocrine system. During the infancy phase, growth is rapid but at a sharply decelerating rate. Growth at this stage is principally dependent on nutrition, although endocrine factors in the form of the growth hormone (GH)-IGF axis play an increasingly important role during the first year of life. Poor growth may be a manifestation of any underlying illness reflecting a wide variety of genetic, constitutional, and pathologic conditions, of which GH deficiency (GHD) is but one cause.[3] Stature itself is merely an indication of a potential abnormal physical state, and is not a diagnosis. The underlying explanation for an abnormal growth process needs to be sought.

By 4 years of age, average height velocity has declined to 7 cm/year, with a further decline to a rate of 5 to 5.5 cm/year at 8 years of age (Fig. 18.1). The onset of the childhood phase of growth is apparent from the age of 6 months, when there is overlap between the childhood and infancy phases of growth. This childhood growth is dependent mainly on endocrine factors such as GH and thyroxine.[4] The third phase of postnatal growth, the pubertal phase, is dependent upon the normal secretion of GH and sex steroids. It is extremely variable in terms of timing, with marked sexual dimorphism that gives rise to the average difference of 12.5 cm in adult height between the sexes.

Growth hormone is the main mediator of postnatal growth,[4] and virtually any chronic childhood illness will modify secretion.

As such, care needs to be exercised in the evaluation of GH secretion in these situations. Although GHD may be considered a form of IGF deficiency, this approach may be limited. Because GH receptor (GHR) and postreceptor issues and GHD in adults are considered elsewhere, this chapter will focus primarily on GHD as related to disorders of the hypothalamo-pituitary axis in children.

KEY POINTS

- The growth of a child is a dynamic process, and is impacted on by prenatal and postnatal factors. Postnatal growth is best described by the Infancy-Childhood-Pubertal (ICP) model, and is regulated by genetic, environmental and hormonal factors.

EPIDEMIOLOGY

The reported incidence of GHD is, to a large extent, dependent on the criteria employed to establish the diagnosis, and reflects the wide variation in the stringency of diagnostic testing. The incidence of congenital isolated GHD varies between 1:4,000 and 1:10,000 live births, depending on the population studied, while 3% to 30% of cases are familial, suggesting a genetic etiology.[5]

Several large surveys have indicated that approximately 25% of children diagnosed with GHD have an underlying "organic" cause for their condition, such as trauma, central nervous system (CNS) tumors, inflammation, irradiation, or anatomic abnormalities of the hypothalamus or pituitary.[6]

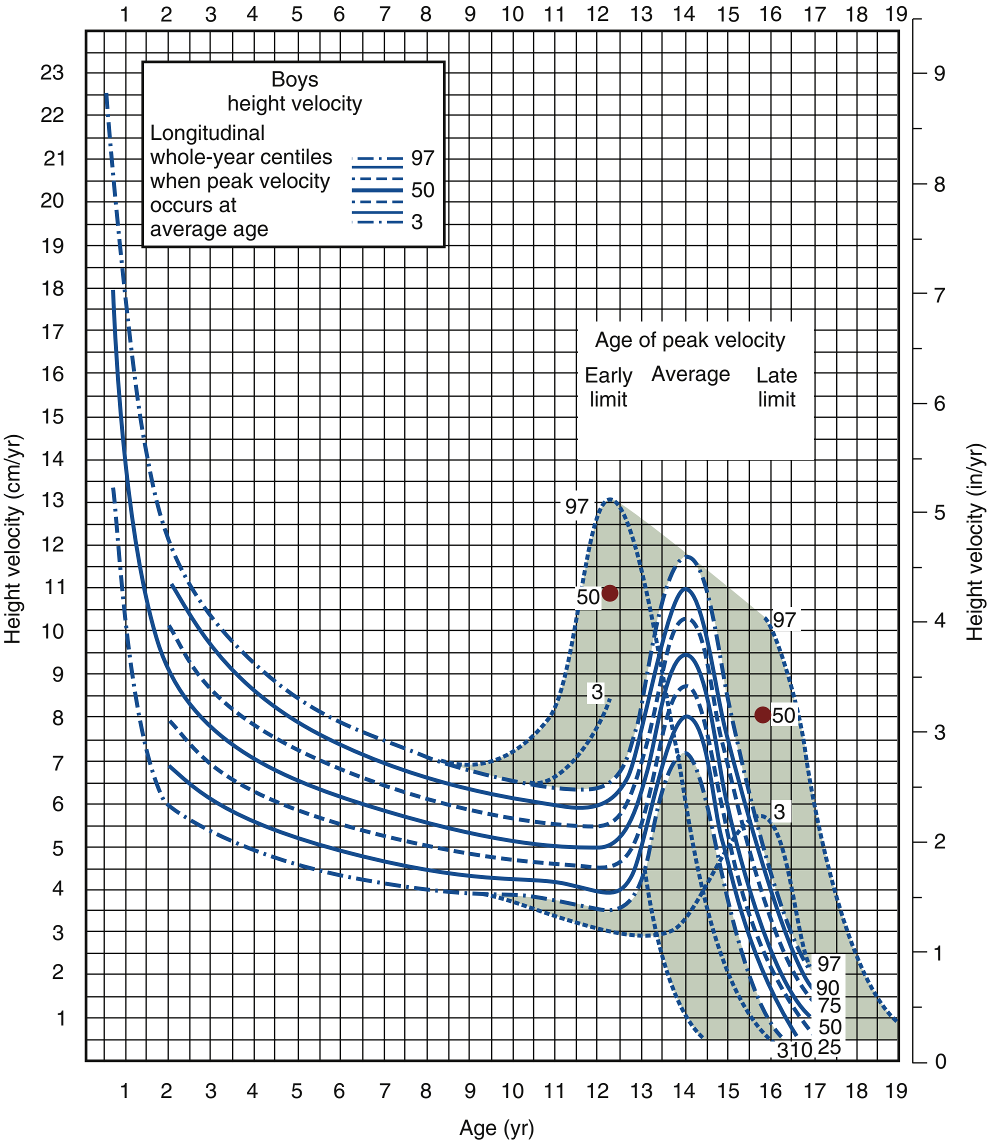

Fig. 18.1 Height velocity chart for boys aged 0–19 years. Centiles 3 to 97 illustrated, with 50th centile in bold. *Shaded zone,* Variation in timing of pubertal growth spurt. Visually, the chart depicts the rapid but rapidly decelerating growth during the first 4 years of life followed by a much slower decline until the onset of the pubertal growth spurt. (Copyright Castlemead Publications.)

The remainder of cases are labeled as "idiopathic" GHD. Such surveys are likely to overestimate the number of true cases of idiopathic GHD because of variation in the diagnosis of GHD. Recent advances in developmental endocrinology suggest that many patients labeled previously as having idiopathic GHD have genetic abnormalities or subtle anatomic abnormalities affecting the hypothalamus, pituitary, or both.

PATHOGENESIS

A list of causes of GHD is provided in Table 18.1. As mentioned already, idiopathic GHD constitutes by far the largest group of patients, although advances in developmental biology are forcing a rethink in this area.

Genetic and Structural Abnormalities

Pituitary Development. The pituitary gland, which consists of anterior, intermediate, and posterior lobes, is a central regulator of growth, metabolism, and development. Its complex functions are mediated via hormone signaling pathways that act to regulate the finely balanced homeostatic control in vertebrates by coordinating signals from the hypothalamus to peripheral endocrine organs (thyroid, adrenals, and gonads). The mature anterior pituitary gland is populated by five neuroendocrine cell types defined by the hormone produced: corticotropes (corticotropin, formerly known as adrenocorticotropic hormone [ACTH]), thyrotropes (thyroid-stimulating hormone [TSH]), gonadotropes (luteinizing hormone [LH], follicle-stimulating hormone), somatotropes (GH), and lactotropes (prolactin [PRL]).[78] The posterior gland secretes vasopressin and oxytocin. The origins of the anterior and posterior lobes of the pituitary gland are embryologically distinct. Rathke's pouch, the primordium of the anterior pituitary, arises from the oral ectoderm, whereas the posterior pituitary derives from neural ectoderm. Development of the anterior gland follows a similar pattern in a number of different species but has been best studied in rodents.[8,9]

In the mouse, anterior pituitary development occurs in four distinct stages: pituitary placode formation; the development of a

rudimentary Rathke's pouch; the formation of a definitive pouch; and finally, the terminal differentiation of the various cell types in a temporally and spatially regulated manner (Fig. 18.2). The apposition of Rathke's pouch and the diencephalon, which later develops into the hypothalamus, is maintained throughout the early stages of pituitary organogenesis[10] and appears to be critical for normal anterior pituitary development. A number of signaling molecules—fibroblast growth factor-8 (FGF8),[10,11] bone morphogenetic protein 4,[10] and NKX2.1,[11]—that are expressed in the neural ectoderm and not in Rathke's pouch are thought to play a significant role in normal anterior pituitary development, as illustrated by the phenotype of mouse mutants that are either null or hypomorphic for these alleles. These signaling molecules activate or repress key regulatory genes encoding transcription factors within the developing Rathke's pouch, such as *Hesx1*, LIM homeobox 3 (*Lhx3*), and LIM homeobox 4 (*Lhx4*), that are essential for the subsequent development of the pituitary.[7,8,10]

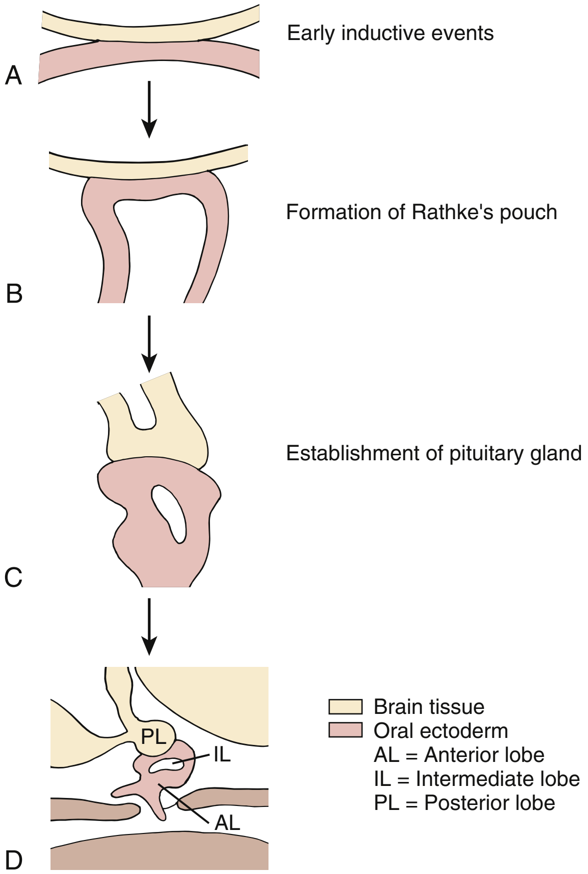

Fig. 18.2 Formation of the pituitary gland. Four-stage process commencing with early inductive events as the infundibulum of the diencephalon abuts the roof of the oral cavity. Pituitary established with signaling gradients generating spatial defined patterns of gene expression and specific cell lineages in the definitive gland. (Reproduced from Valette-Kasic and Enjalbert, *Topical Endocrinology*, February 2003.)

The final stage of pituitary gland development entails the terminal differentiation of the progenitor cells into the distinct cell types found within the mature pituitary gland. This process is tightly regulated by extrinsic factors (Fgf8, Bmp2, Bmp4, and Bmp7) that emanate from the surrounding infundibulum and the juxtapituitary mesenchyme. These then establish gradients of transcription factors (Lhx3, Six3, prophet of Pit1 [Prop1], Pou1f1 (Pit1), Nkx3.1, Islet-1, Lhx4, Six1, Brain-4, and pituitary forkhead).[11] These genetic gradients lead to a wave of cell differentiation. Each of the five anterior pituitary cell types differentiates in a temporally and spatially regulated manner (Fig. 18.3),[12] and this process is dependent upon a number of transcription factors such as Pou1f1, Tpit, and steroidogenic factor 1.[13]

In this multistep process, somatotropes appear by embryonic day (E)15.5 in the anterolateral wings of the developing gland, following the appearance of corticotropes and thyrotropes. The onset of expression of the activator Prop1 by E12.5 and its maintenance until E15.5 is a critical step, as it is required for the emergence of the Pou1f1 lineage

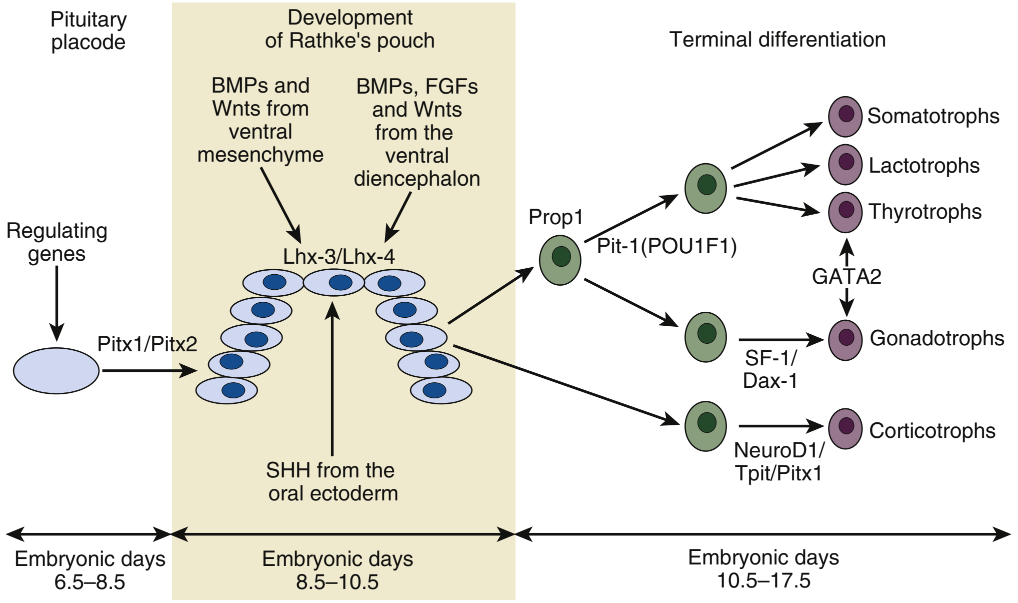

Fig. 18.3 Temporal sequence of events of pituitary development in the mouse. *BMP,* Bone morphogenetic protein; *SHH,* sonic hedgehog; *FGF,* fibroblast growth factor. (Reproduced from Valette-Kasic and Enjalbert, *Topical Endocrinology*, February 2003.)

(somatotropes, lactotropes, thyrotropes). In turn, Pou1f11 is detected by E13.5 and reaches its peak level of expression in the differentiated somatotrophs by E16, and its expression is maintained in adulthood. Activation of Pou1f1 is required for the production of GH, the expression of GH-releasing hormone receptor (GHRHR), and the postnatal expansion of GH-producing cells. The appearance of differentiated somatotropes is followed by a dramatic increase in their number and their migration by E18.5 throughout the central and lateral parts of the anterior lobe.[14] The preferential distribution of somatotropes in this location does not seem to depend on their time of exit from the cell cycle,[15] but is rather a dynamic process during which somatotropes migrate to form homotypic three-dimensional networks.[16] Recent elegant imaging studies reveal that this organization of somatotropes is not merely topographic, but that somatotropes are organized into a functional and structural network that facilitates their coordinated physiological response to different stimuli.[17] This organization into a cellular continuum is maintained postnatally, thus ensuring the plasticity of the system and its adaptation throughout life.[18] Although less is known about pituitary development in humans, it appears to mirror that in the rodent. Spontaneous or artificially induced mutations in the mouse have led to significant insights into human pituitary disease, and identification of mutations associated with human pituitary disease have in turn been invaluable in defining the genetic cascade responsible for the development of this complex structure.[8]

Syndromic Growth Hormone Deficiency in Humans. A number of genetic abnormalities have been identified in children who were previously thought to have idiopathic GHD or combined pituitary hormone deficiency (CPHD) (Table 18.2).[19]

Mutations in early transcription factors may result in GHD in association with other developmental abnormalities, such as septooptic dysplasia (SOD), skeletal defects, or intellectual impairment with or without the development of other pituitary hormone deficiencies.

For instance, mutations within the paired-like homeobox gene *HESX1* are associated with the phenotypes of GHD, CPHD, and SOD, a condition characterized by forebrain, pituitary, and eye abnormalities such as optic nerve hypoplasia.[20]

The inheritance and phenotypes are variable, with both dominant and recessive modes of inheritance described. *HESX1* mutations are an uncommon cause of hypopituitarism, representing less than 1% of cases,[21] and have been described in patients with variable phenotypes without obvious genotype-phenotype correlation. Intriguingly, *HESX1* mutations are classically associated with anterior pituitary hypoplasia with an undescended posterior pituitary and an absent or thin infundibulum.[22] On rare occasions, heterozygous *HESX1* mutations (p.E149K, p.S170L, p.T181A) may be associated with isolated GHD in patients with relatively milder phenotypes compared with the classic manifestations of SOD, who may or not have optic nerve hypoplasia, while an ectopic/undescended posterior pituitary and anterior pituitary hypoplasia are not always present (p.S170L)[21]

Orthodentic homeobox 2 (OTX2) is another early transcription factor that is important for the formation of anterior structures and the forebrain and has been implicated in the etiology of 2% to 3% of anophthalmia/microphthalmia syndromes in humans.[23]

The pituitary phenotype of patients with heterozygous *OTX2* mutations ranges from partial to complete GHD or hypopituitarism with or without an ectopic posterior pituitary on magnetic resonance imaging (MRI). There is no clear genotype-phenotype correlation, even among patients with the same mutation, and, in rare cases, patients may not even exhibit an ocular phenotype (p.N233S).[24,25,26] As there are no long-term follow-up data for patients with heterozygous *OTX2* mutations who present with isolated GHD, careful monitoring for the development of additional endocrinopathies is needed.

Mutations within the LIM-domain genes *LHX3* and *LHX4* are associated with CPHD with extrapituitary manifestations such as a rigid neck (70% of patients), vertebral anomalies, and more or less severe hearing loss (50% of cases) in the case of *LHX3*,[22] and an abnormal cerebellum in the case of *LHX4*.[27] The inheritance of *LHX3* mutations is recessive, whereas that associated with *LHX4* mutations is dominant, unlike the murine phenotype.

To date, all reported patients with heterozygous *LHX4* mutations have had GHD and short stature on presentation, in association with variable endocrine deficits or panhypopituitarism. However, there is remarkable variability in the phenotype even within the same family,

TABLE 18.2 List of Genes with Reported Pathogenic Variants Known to Cause Hypothalamo-Pituitary Disease[13]

Gene with Reported Variants	Phenotype	Mode of Inheritance
ARNT2	CPHD, congenital abnormalities of the kidneys and urinary tract	Recessive
CDON	PSIS	Dominant
EIF2S3	GHD, TSHD, glucose dysregulation, MEHMO syndrome	X-linked
FGF8	HH/KS; HPE	Dominant/recessive
FGFR1	HH/KS, SOD	Dominant
FOXA2	CPHD, HI, childhood-onset diabetes, choroidal coloboma, biliary atresia (cardiac/ endoderm-derived organ abnormalities)	Dominant
GH1	IGHD type IA	Recessive
	IGHD type IB	Recessive
	IGHD type II	Dominant
GHRHR	IGHD type IB	Recessive or dominant (rare)
GLI2	HPE, IGHD/CPHD, polydactyly, single central incisor	Dominant: haploinsufficiency
GPR161	PSIS	Recessive
HESX1	IGHD, CPHD, SOD	Dominant or recessive
IFT172	GHD, retinopathy, metaphyseal dysplasia, renal failure (ciliopathies)	Compound heterozygous
IGSF1	TSHD, hypoprolactinemia, transient GHD; usually with macroorchidism	X-linked
KAL1	HH/KS	X-linked
KCNQ1	GHD, maternally inherited gingival fibromatosis	Dominant
LHX3	CPHD, short neck with limited rotation	Recessive
LHX4	CPHD, Chiari malformation, cerebellar abnormalities, respiratory distress	Dominant or recessive
OTX2	IGHD, CPHD, SOD, anophthalmia/microphthalmia, retinal dystrophy	Dominant: haploinsufficiency or dominant negative
PCSK1	IAD, GHD, TSHD, DI, malabsorption	Dominant, compound heterozygous
PNPLA6	Oliver–McFarlane and Laurence–Moon syndrome; GH and gonadotrophin deficiencies	Recessive
POMC	IAD; early-onset obesity and red hair pigmentation	Recessive
POU1F1	GH, TSH, and ACTH deficiencies	Dominant or recessive
PROKR2	HH/KS	Recessive
PROP1	CPHD, pituitary tumors	Recessive
RAX	Anophthalmia/microphthalmia, CPHD, DI, and cleft palate	Recessive or compound heterozygous
RNPC3	IGHD	Recessive
ROBO1	PSIS	Dominant
SOX2	HH, anophthalmia/microphthalmia, learning difficulties, hypothalamo- pituitary tumors	Dominant
SOX3	GHD, CPHD, absent infundibulum, persistent craniopharyngeal canal	X-linked
TBL1X	TSHD, ASD	X-linked
TBX19	IAD	Recessive
TCF7L1	SOD	Dominant
TRHR	TSHD	Recessive
TSHB	TSHD	Recessive

>*CPHD*, Combined pituitary hormone deficiency; *PSIS*, pituitary stalk interruption syndrome; *GHD*, growth hormone deficiency; *TSHD*, thyroid-stimulating hormone deficiency; *MEHMO*, mental retardation, epileptic seizures, hypogonadism with hypogenitalism, microcephaly, and obesity; *HH*, hypogonadotropic hypogonadism; *KS*, Kallmann syndrome; *HPE*, holoprosencephaly; *SOD*, septooptic dysplasia; *HI*, congenital hyperinsulinism; *IGHD*, isolated growth hormone deficiency; *IAD*, isolated adrenocortical deficiency; *DI*, diabetes insipidus; *ASD*, autism spectrum disorder; *GH*, growth hormone; *TSH*, thyroid-stimulating hormone; *ACTH*, adrenocorticotropic hormone.

ranging from panhypopituitarism to GHD with partial TSH deficiency, or even partial GHD and short stature, diagnosed later in life.[27] Recently, a homozygous mutation in *LHX4* was identified in a pedigree of Pakistani origin with a phenotype characterized by severe anterior pituitary hypoplasia associated with severe early hypopituitarism and neonatal death in all affected siblings.[28]

Homozygous variants of *LHX3* lead to combined pituitary hormone deficiency, displaying consistent somatotrope, thyrotrope, and gonadotrope deficits, and inconsistent corticotrope deficits. On MRI, the pituitary was described as hypoplastic or aplastic in 60% of cases, normal in 10%, and hyperplastic in 30% of cases. There are also studies demonstrating the possibility that patients with a heterozygous variant of *LHX3* may have pituitary deficiencies, with a milder phenotype than patients with homozygous variants. It is thus vital to propose optimal follow-up of such patients who, until now, were considered as not being at risk of presenting pituitary deficiency.[29]

Mutations within the gene encoding the transcription factor Sox2 are associated with hypopituitarism in mouse and humans. *SOX2* is one of the earliest known genes to be expressed in embryonic stem cells and neural progenitors. Although mutations in the mouse are associated with a generalized reduction in all pituitary cell types, in humans the most frequent pituitary defect is hypogonadotropic hypogonadism, with GHD being less frequent. Other features include eye disorders (anophthalmia and microphthalmia), brain malformations (usually hippocampal), intellectual disabilities, esophageal atresia, genital abnormalities, sensorineural hearing loss, and a hypoplastic anterior pituitary.[30] Pituitary masses have been observed in affected patients, but they do not progress.[31]

Studies with *SOX3* suggest a possible explanation contributing to the predominance of males in many series of GHD, as it is now a recognized cause of X-linked or type III GHD. *SOX3* is located on the X chromosome (Xq26–27) and appears to not only be important for pituitary development but also to be associated with mental retardation.[32] These observations of GHD and brain developmental abnormalities are particularly important, because neurodevelopmental handicap has often been ascribed to untreated neonatal hypoglycemia, whereas structural developmental problems may be a more pertinent explanation. Patients with over- or underdosage of *SOX3* present with isolated GHD or combined pituitary hormone deficiencies or normosmic hypogonadotropic hypogonadism, with or without mental retardation or learning difficulties, and an ectopic/undescended posterior pituitary on MRI.[33]

In different pedigrees, large or submicroscopic duplications at the Xq26–27 locus encompassing *SOX3* have been associated with a phenotype. In addition, expansion of the first polyalanine tract of SOX3 by 7 or 11 residues or an in-frame deletion resulting in the loss of six alanine residues have been reported in association with variable phenotypes (isolated GHD or combined pituitary hormone deficiencies).[34] The variability in the size of the polyalanine tract in SOX3 is an uncommon cause of hypopituitarism or isolated GHD, and to date there have been no reported point mutations in *SOX3* leading to functional compromise.

Retina and anterior neural fold homeobox (RAX) is a transcription factor involved in eye and forebrain development. Bilateral microphthalmia or anophthalmia in some patients has arisen from compound heterozygous or recessive *RAX* mutations.[35] A severe clinical phenotype has recently been described in a patient with a homozygous truncating *RAX* mutation.[32] The patient showed anophthalmia, GH, TSH, and ACTH deficiencies with probable gonadotropin deficiency, diabetes insipidus (DI), bilateral cleft lip and palate, micropenis, and absent anterior and posterior pituitary with a rudimentary pituitary stalk.[36]

Roundoabout 1 (ROBO1) is one of the four mammalian genes encoding Roundabout receptors, and is involved in neurogenesis, angiogenesis, and cell proliferation. Heterozygous nonsense or missense *ROBO1* mutations have been described in subjects with pituitary stalk interruption syndrome (PSIS) with various hormone deficiencies and ocular anomalies such as strabismus or ptosis. Slit-Robo signaling is also implicated in mouse heart development, and loss-of-function variants in *ROBO1* have been reported in patients with ventricular septal defect and tetralogy of Fallot. Pituitary stalk duplication, hypoplastic anterior pituitary, and ectopic posterior pituitary have recently been described in two family members with a *ROBO1* deletion.[37]

Aryl-hydrocarbon receptor nuclear translocator 2 (ARNT2) is a member of the basic-helix-loop-helix-Per-Arnt-Sim superfamily of transcription factors. ARNT2 mutations are associated with CPHD involving congenital abnormalities of the kidneys and urinary tract. A homozygous frameshift *ARNT2* mutation has been described in six patients from a highly consanguineous pedigree with CPHD, postnatal microcephaly, frontotemporal lobe hypoplasia, and visual and renal abnormalities.[38]

De novo heterozygous mutations in *forkhead* box A2 (FOXA2) have been reported in syndromic forms of CPHD associated with congenital hyperinsulinism, craniofacial dysmorphism, choroidal coloboma, and lung and gastrointestinal malformations. In addition, cases with childhood-onset diabetes and cardiac malformations have recently been described.[39]

MAGE family member L2 (MAGEL2) is a member of the type II MAGE gene family involved in neurogenesis and brain function. MAGEL2 mutations have been recently described in pedigrees with CPHD associated with arthrogryposis.[40]

Hemizygous missense and frameshift mutations in eukaryotic translation initiation factor 2 subunit 3 (EIF2S3) have been described in patients with MEHMO syndrome, an X-linked disorder characterized by GHD, mental retardation, seizures, hypogonadism, microcephaly, and obesity.[41]

TBC1 domain family member 32 (TBC1D32) is a gene involved in ciliary function and sonic hedgehog (SHH) signaling. Biallelic loss-of-function variants in *TBC1D32* have recently been described in two Finnish siblings with CPHD, absent anterior pituitary, and mild craniofacial dysmorphism, and in a Pakistani child with GHD, anterior pituitary hypoplasia, and developmental delay.[42]

Potassium voltage-gated channel subfamily Q member 1 (KCNQ1*)* is known to be associated with cardiac arrhythmia syndromes. A clinical phenotype characterized by GHD and gonadotropin deficiencies associated with maternally inherited gingival fibromatosis has recently been described in subjects from three unrelated families with missense *KCNQ1* mutation.[43]

Two variants in *transcription factor 7-like 1* (TCF7L1) associated with forms of SOD in humans have been described.[25] The first variant, p.R92P, has been reported in a male infant with partial agenesis of the corpus callosum, thin anterior commissure, right optic tract hypoplasia, and low IGF1 concentrations. The second variant, p.R400Q, has been described in a male infant with bilateral optic nerve hypoplasia, anterior pituitary hypoplasia, absent septum pellucidum, and posterior pituitary bright spot.[44]

Holoprosencephaly (HPE) is a congenital defect of the brain characterized by incomplete cleavage of the embryonic forebrain into left and right hemispheres. It is characterized by variable degrees of defects in the separation of the cerebral hemispheres and ventricles, while failure of the frontal and parietal lobes to divide posteriorly results in an absent corpus callosum. HPE is commonly characterized by midline facial defects, ranging from cyclopia or anophthalmia to midfacial hypoplasia, cleft lip and palate, and a single central incisor.[45] DI is common, but anterior pituitary hormone deficiencies have also been described. An increasing number of genes are implicated in its etiology, including genes encoding members of the SHH signaling pathway such as *SHH*, *ZIC2*, *TGIF1*, *PTCH1*, *GLI2*, *DISP1*, *TDGF1*, *GAS1*, *EYA4,* and *FOXH1*. Heterozygous mutations in *GLI2* have been reported in patients with variable craniofacial abnormalities, isolated GH deficiency (IGHD) or CPHD, and pituitary hypoplasia. In addition, mutations in *FGF8* have been identified as the first genetic cause of autosomal recessive HPE.

More recently, a mutation in *CDON*, a SHH coreceptor and a component of the SHH signaling pathway previously implicated in the etiology of HPE, has been identified in a patient with PSIS with GH, TSH, and ACTH deficiencies, as well as neonatal hypoglycemia and cholestasis.[46] Interestingly, a murine Cdon mutation was associated with optic nerve hypoplasia, and the effect was phenocopied by ethanol administration.[47] A recessive variant in a further SHH component, GPR161, encoding the orphan G protein–coupled receptor 161, has also been reported in a consanguineous family with PSIS.[48] These data suggest that the SHH signaling pathway is critical for normal hypothalamo-pituitary (HP) development.

Compound heterozygosity for mutations in *IFT172* was identified in a patient with early growth retardation, anterior pituitary hypoplasia and an ectopic posterior pituitary, in addition to retinopathy, and hypertension with renal failure. The phenotype was consistent with a ciliopathy,[49] and was the first report of a mutation in this gene associated with a pituitary defect. *IFT172* encodes an intraflagellar transport subcomplex subunit that is essential for ciliary assembly and maintenance. Previously, mutations have been described in skeletal ciliopathies with variable polydactyly, as well as retinal, cerebellar, or hepatorenal malformations.[50] Consistent with these data, Alstro¨m syndrome, a rare autosomal recessive disease, consists of multiorgan dysfunction with GHD and is caused by mutated *ALMS1,* which encodes a protein localizing to centrosomes and basal bodies of ciliated cells.[51] These studies imply a critical emerging role for cilia in HP development.

It is clear that our understanding of the etiology of hypopituitarism and the mechanisms whereby mutations lead to a particular phenotype is rudimentary and evolving. Additionally, many cases of hypopituitarism may be due to changes in regulatory regions of known genes or perhaps within novel genes that have yet to be identified. The role of epigenetic factors cannot be discounted, and could be contributory to those cases of hypopituitarism that are unexplained.

Growth Hormone-Releasing–Hormone and Its Receptor. Because growth hormone–releasing hormone (GHRH) and its receptor (GHRHR; GHD type 1B) are critical to somatotrope population expansion, abnormalities in either are likely to be associated with severe GHD. No mutations of the human *GHRH* gene have been identified to date,[52] but mutations in *GHRHR* have been identified in a number of pedigrees.[53,54] In most cases, patients were of consanguineous pedigrees or from specific ethnic backgrounds.

With one exception,[55] all patients reported to date have been either homozygous or compound heterozygous for mutations of the *GHRHR* gene. Children have severe GHD and short stature but, compared with those with recessive *GH1* mutations, midfacial hypoplasia, neonatal hypoglycemia, and microphallus are not common. Serum GH concentrations fail to rise following standard provocative testing, as well as after GHRH administration. Because of the effect of GHRH on the proliferation of somatotropes, anterior pituitary hypoplasia on MRI is almost an invariable finding; the conflicting reports of apparently normal pituitary morphology in patients with the same *GHRHR* mutation[56] may be explained by the different age groups and lack of age-matched reference standards. However, recently a milder form of GHD was reported in association with a novel partial loss-of-function mutation in *GHRHR*.[57]

Mutations in Late Transcription Factors Affecting Somatotrope Development. A number of mouse models exist in which somatotrope development has been impaired. These include the Ames, the Jackson, and the Snell dwarf mice. A missense point mutation within the *PROP1* gene (S83P) has been shown to be responsible for the Ames dwarf mouse.[58] The phenotype results from a failure of initial determination of the Pit1 lineage required for production of GH, PRL, and TSH. The Ames pituitary gland contains less than 1% of the normal complement of somatotropes and decreased numbers of lactotropes and thyrotropes. In humans, mutations within the transcription factor Prop1 are associated with CPHD in the form of GH, PRL, TSH, and gonadotropin deficiency, while a proportion of individuals with *PROP1* mutations will develop cortisol deficiency.[59] Additionally, a number of individuals with mutations within *PROP1* develop transient pituitary masses that can wax and wane,[60] with subsequent involution (Fig. 18.4).[61] The exact mechanism underlying this phenomenon remains unclear, but it is clearly important to exclude mutations within *PROP1* in patients with pituitary "tumors," especially the nonfunctioning variety. There is considerable variability in the timing of the endocrinopathy: a number of patients will actually commence puberty but then arrest halfway through, others may present in childhood with growth hormone deficiency before the gradual development of TSH, PRL, and gonadotropin deficiency later in life, and in rare cases somatotrope function may be retained, as in the report of a patient who attained normal final height without GH replacement.[59,62] Pit1 (now known as Pou1f1) is a member of the POU family of homeodomain proteins and contains a highly conserved bipartite DNA-binding domain consisting of the POU homeodomain, required for low-affinity DNA binding, and a POU-specific domain, responsible for the specificity of DNA binding and potential interactions with other proteins.[59,63] The Snell dwarf mouse, characterized by pituitary hypoplasia and GH, PRL, and TSH deficiencies, has a point mutation (W261C) within the *Pit1* gene, affecting the third helix of the POU homeodomain. This abrogates binding of Pit1 to its target promoter sequences. Several mutations and deletions of the *POU1F1* gene have been identified in humans with CPHD, characterized by the combination of GH, PRL, and TSH deficiency.[63] Mutations have been described that separately affect the DNA-binding capacity of POU1F1 or its transactivation properties. Autosomal dominant transmission, resulting from a dominant negative effect, has been observed in mutations affecting POU1F1 dimerization or transactivation (p.P24L), or in the relatively common p.R271W mutation, which results in increased binding to promoter elements and disruption of transcriptional activation. Autosomal recessive transmission is found with other mutations, such as p.A172X, p.E250X, p.R143G, p.A158P, and p.P239S. Variability in phenotype has been reported, although most patients exhibit growth retardation during the first year of life.[64] GH and PRL deficiencies are complete; TSH secretion may be observed during infancy but declines progressively during the early months of life. MRI scanning revealed a marked variability in the size of the anterior pituitary, with some patients demonstrating a normal pituitary and others having a hypoplastic pituitary. After appropriate GH and thyroxine replacement, patients appear to enter puberty normally and have normal fertility. Lactation may be impaired. In some patients, TSH secretion may be normal.[64] A recent study has described the phenotype of isolated GHD in association with a heterozygous dominant mutation in *POU1F1*, p.Pro76Leu.[65]

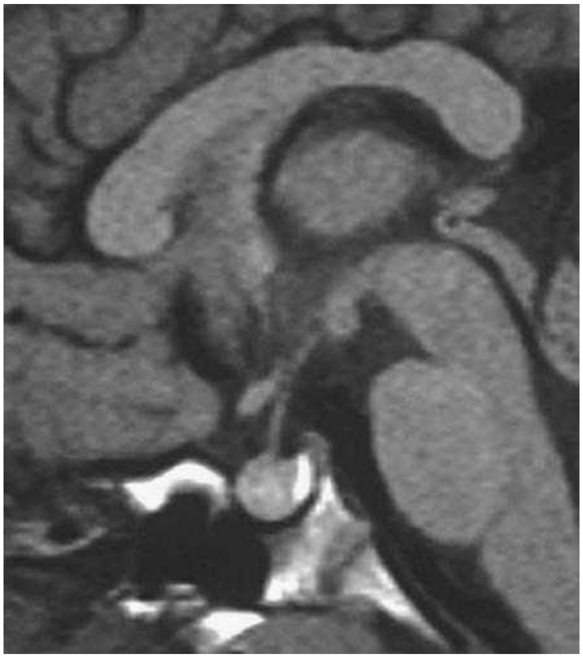

Fig. 18.4 **Pituitary "tumor" in patient with *PROP-1* mutation.** Saggital magnetic resonance imaging scan of the pituitary revealing a large, globular anterior pituitary with normal posterior pituitary enhancement. Subsequent scans revealed involution of the mass and resultant empty sella.

***GH1* Gene.** The *GH1* gene, located at chromosome 17q22-24, is part of a cluster of five structurally related genes: *GH1*, chorionic

TABLE 18.3 **Genetic Abnormalities in GH1**

Type	Inheritance	Gene(s)	Mutations	Phenotype
IA	Autosomal recessive	*GH1* (OMIM #139250)	Deletions (6.7–45 kilobases) Frameshift Nonsense	Undetectable GH, anti-GH antibodies on rhGH treatment
IB	Autosomal recessive	*GH1* (OMIM #139250)	Splice site Missense Nonsense Frameshift	Low, detectable GH; no antibodies on rhGH treatment
II	Autosomal dominant	*GH1* (OMIM #139250)	Splice site Splice site enhancers Missense	Variable short stature (severe to normal height); may have evolving MPHD
III	X-linked recessive	*SOX3* (OMIM #313430) *BTK* (OMIM #300300), unknown	PA tract deletions/expansions Gene deletions/duplications	IGHD or MPHD; ectopic posterior pituitary +/- mental retardation +/- agamma/hypogammaglobulinaemia
IV	Autosomal recessive	*GHRHR* (OMIM #139191)	Splice site Missense Nonsense	Extremely low GH concentrations, good response to rhGH treatment, can be milder phenotype (midfacial hypoplasia, neonatal hypoglycaemia, microphallus less common)
V	Autosomal recessive	*RNPC3* (OMIM #618016)	Missense	Severe postnatal growth failure, undetectable GH, low-normal PRL concentrations, may have multiple pituitary hormone deficiency, high total ghrelin concentrations (normal acylated ghrelin)

OMIM, Online Mendelian Inheritance in Man; *GH*, growth hormone; *rhGH*, recombinant human growth hormone; *IGHD*, isolated growth hormone deficiency; *MPHD*, multiple pituitary hormone deficiency; *PA*, polyalanine; *PRL*, prolactin.

somatomammotropin pseudogene (*CSHP*), chorionic somatomammotropin (*CSH*), *GH2* (or placental variant), and *CSH2*. Mutations within the *GH1* gene are associated with isolated GH deficiency (Table 18.3).[66] Large, recessive, inherited deletions are associated with an absence of GH-protein (type 1A, autosomal recessive GHD). Complete loss of pituitary GH secretion occurs secondary to deletions resulting from nonhomologous crossing over at different sites in the GH and chorionic somatomammotropin gene clusters. The most common deletion is 6.7 kb, but deletions of 7.0, 7.6, and greater than 45 kb have also been observed.[66] Patients typically present with severe growth failure (height standard deviation score [SDS] <–4.5) by the first 6 months of age and have an excellent initial response to GH therapy, but, because of the absence of a normal GH molecule in fetal life, an attenuation of the growth response to exogenous GH may result from the development of anti-GH antibodies, although this event has been described less frequently with newer GH preparations.[67]

Type IB GHD is due to homozygous splice-site, frameshift, and nonsense mutations within the *GH1* gene or homozygous or compound heterozygous mutations within *GHRHR*. Children with type IB GHD present with marked short stature, poor growth velocity, low but detectable GH concentrations, and an excellent response to GH treatment, with no formation of antibodies. In some families, unaffected carriers of the mutant allele may have significantly shorter stature than noncarriers.[67]

Type II GHD is autosomal dominant and associated with splice-site mutations. These mutations lead to the production of two alternatively spliced GH molecules, 20- and 17.5-kD human pituitary-derived GH (hGH). Mutations in an exon splice enhancer within exon 3 of the *GH1* gene have also been associated with autosomal dominant GHD.[68] The generation of the 17.5-kD form of hGH has a dominant negative effect and prevents the secretion of the normal wild-type 22-kD hGH, with a consequent deleterious effect on pituitary somatotropes. In a murine model of this dominant negative mutation, there is loss of somatotroph number[69] and progressive damage to adjacent pituitary cells (with later failure of PRL, TSH, and gonadotropin secretion).[70] In addition, missense mutations (p.R183H, p.P89L, and p.V110F) are also implicated in IGHD type II. These patients have a normal *GH1* allele but are unable to secrete the normal form of GH in appropriate concentrations. The mutant protein therefore exerts a dominant negative effect. As in the mouse, evolution of other hormonal deficiencies, including ACTH, TSH, and gonadotropin deficiencies, have been described in patients with some dominant *GH1* mutations.[71]

GHD type III, an X-linked form of IGHD, has been reported in patients with hypogammaglobulinemia. The role of the transcription factor SOX3 in the development of GHD with/without mental retardation has already been mentioned in a previous section of this chapter.

Bioinactive Growth Hormone Molecule. Because the GH molecule exists in multiple molecular forms resulting from alternative splicing or posttranslational processing, some cases of short stature have been hypothesized to be the consequence of abnormal ratios of the various GH forms. Heterozygous missense *GH1* mutations may impair growth by a complex mechanism that affects not only the secretion of GH, but also its bioactivity. Two individuals heterozygous for point mutations in *GH1* were described by Takahashi et al.,[72] who detailed the biochemistry and molecular genetics. The mutant GH molecules (p.R77C and p.D112G) were capable of binding to the GHR, perhaps even with increased affinity, but were unable to stimulate tyrosine phosphorylation of GH-activated intracellular signaling intermediates in a normal manner. The ability of the p.R77C mutant to behave in a dominant negative manner was demonstrated by its capacity to inhibit the *in vitro* actions of wild-type GH. Subsequently, the heterozygous p.R77C mutation has been reported in patients with growth retardation and delayed pubertal development, who showed normal catch-up growth with recombinant human GH (rhGH) replacement therapy.[73] However, there is no clear phenotype-genotype correlation, as family members of normal stature were also carriers. In this case, patients do not always have short stature, and they may have normal or slightly increased GH secretion and low IGF1 and GH binding protein (GHBP) concentrations. Recent *in vitro* studies did not show any difference between the mutant and wild-type GH molecule in terms of binding to the GHR and activation of the downstream Jak2/Stat5 pathway.[73] However, it is possible that the mutation results in reduced capability to induce the transcription of the genes encoding GHR and GHBP.[60] Missense *GH1* mutations (p.P59L and p.P59S)[74] may result in reduced binding affinity for the GHR, while in some cases (p.R178H) the mechanism of action is more complex, with the mutation affecting both GH and GH binding affinity for the GHR, resulting in reduced activation of the downstream signaling pathway.[75]

RNPC3 and GHD. Compound heterozygous mutations in *RNPC3*, encoding the RNA-binding region containing 3, a 65-kD protein that is a component of the U12-dependent spliceosome, have been associated with the IGHD phenotype. Both mutations, namely a missense mutation (p.P474T) and a nonsense mutation (p.R502X), were shown to impair the binding of the U11/U12-65K protein encoded by *RNPC3* to U12 and U6atac snRNAs. The two mutations therefore reduce the formation of the U12-type intron recognition complex, leading to defects of splicing in a subset of minor introns.[76] A more recent study described the presence of compound heterozygosity for two variants in *RNPC3*, namely c.443G>C, p.(G148A), and c.259C>T, p.(Q87X), in three siblings from a Caribbean pedigree. All three affected children manifested a phenotype characterized by CPHD (GH, TSH, and PRL deficiencies), as well as learning difficulties and congenital cataracts.[77]

Structural Abnormalities. In addition to the structural abnormalities associated with the genetic problems described above, GHD can occur in the setting of other cranial or midline abnormalities such as holoprosencephaly, nasal encephalocele, single central incisor, and cleft lip and palate.

As methods of radiologic evaluation of the CNS have improved, an increasing percentage of patients with idiopathic GHD have been identified to have structural abnormalities.[78] Many of these are associated with some of the genetic abnormalities described above, but the findings are worthy of separate consideration. In particular, earlier studies showed that the finding on MRI of an undescended (frequently called "ectopic") posterior pituitary (posterior pituitary ectopia [PPE]) was commoner in males than females (3:1 when PPE present vs. 1:1 if normal anatomy), in patients with CPHD as compared with IGHD (49% vs. 12%), breech delivery (32% vs. 7%), and associated congenital brain anomalies (12% vs. 7%).[79]

These findings appear to be best explained by a defect in induction of the mediobasal structure of the brain in the early embryo rather than the product of birth trauma, as previously suggested. Whether pituitary insufficiency is the result of hypothalamic or pituitary dysgenesis, or the product of hypoplasia or sectioning of the pituitary stalk, is not always clear. Perinatal problems, however, including breech presentation, may prove to be the *consequence* rather than the *cause* of underlying CNS abnormality. The concept that PPE, stalk section or hypoplasia, and pituitary hypoplasia may represent abnormal embryonic development rather than the consequences of birth trauma is supported by the finding of similar anatomic abnormalities in patients with SOD, type I Arnold-Chiari syndrome, and holoprosencephaly, and increasingly in patients with mutations in the genes controlling pituitary development.

In the empty sella syndrome, abnormalities of the sellar diaphragm allow herniation of the suprasellar subarachnoid space into the region of the sella turcica.[80] This may result in damage to the sella, including the pituitary. Empty sella syndrome may be the consequence of surgery or irradiation or may be idiopathic. It is often found in patients with mutations in *PROP1*, when it may have been preceded by a pituitary mass.

Acquired Defects

A wide range of destructive lesions involving the hypothalamus or pituitary may present with isolated GHD or CPHD. Birth trauma, associated with abrupt delivery, prolonged labor, or extensive use of forceps, has been associated frequently with subsequent hypothalamic or pituitary dysfunction.[81]

Destructive Lesions of the Hypothalamus and Pituitary. An increased incidence of GHD has been reported in breech deliveries, although it is still unclear whether such deliveries lead to the acquisition of pituitary dysfunction or, on the other hand, whether preexisting CNS abnormalities result in higher rates of abnormal birth presentations.

Tumors. CNS tumors are an important cause of isolated GHD and CPHD and must be excluded in every child with GHD who does not have an obvious alternative explanation for growth failure.

Midline brain tumors include germinomas, meningiomas, gliomas, colloid cysts of the third ventricle, ependymomas, and optic nerve gliomas. GHD or CPHD may also occur from local extension of tumors affecting the head or neck, such as craniopharyngeal carcinomas and lymphomas.

The major pediatric tumor involving the pituitary is the craniopharyngioma, which is probably an evolving congenital malformation that develops from remnants of Rathke's pouch.[82] It accounts for 5% to 15% of intracranial tumors in childhood and 80% of tumors in the HP region. Arising from rests of squamous cells at the embryonic junction of the adenohypophysis and neurohypophysis, it forms an enlarging cyst filled with degenerating cells, leading to cyst fluid or calcification but never to malignant degeneration (Fig. 18.5). These calcifications may be seen at times on skull films and constitute an important diagnostic sign. Although craniopharyngiomas represent the consequences of a congenital malformation, they may present clinically at any age. Significant growth failure may be observed in 30% to 50% of children at the time of diagnosis,[83] but patients most commonly present with complaints of increased intracranial pressure, such as headaches, vomiting, and oculomotor disturbances; visual field defects are frequently noted at the time of diagnosis. Deficiency of at least one pituitary hormone, most commonly GH or gonadotropin, is present in 50% to 80% of patients. DI is reported in 25% to 50% of patients at diagnosis.[82,83] The variation in the reported incidence of DI may be due to the fact that incidence of DI is either underestimated or may be masked by the simultaneous presence of ACTH deficiency.

The commonest type of craniopharyngiomas in childhood is adamantinomatous craniopharyngioma (ACP). Activating mutations in the gene encoding β-catenin (*CTNNB1*), a component of the Wnt signaling pathway, have long been identified in ACPs.[84] A murine model that expresses a degradation-resistant mutant form of β-catenin in early progenitors of Rathke's pouch has furthered our understanding.[85] Most mutant mice die perinatally, by 4 weeks of age, and those who survive exhibit pituitary hyperplasia and marked hypopituitarism with severe disruption of the differentiation of the POU1F1 lineage and extreme growth retardation. Ultimately, all animals develop lethal pituitary tumors that closely resemble human ACPs. The tumorigenic effect of the activated mutant β-catenin is observed only when it is expressed in undifferentiated progenitors, demonstrating that mutated β-catenin in pituitary progenitor/stem cells has a causative role in the etiology of murine tumors resembling human ACPs.[85]

Pituitary adenomas, dermoid or epidermoid cysts, lipomas ,and teratomas are less frequent causes of GHD in childhood.[86]

Langerhans cell histiocytosis (LCH) may also present at any age. LCH is characterized by clonal proliferation and accumulation of

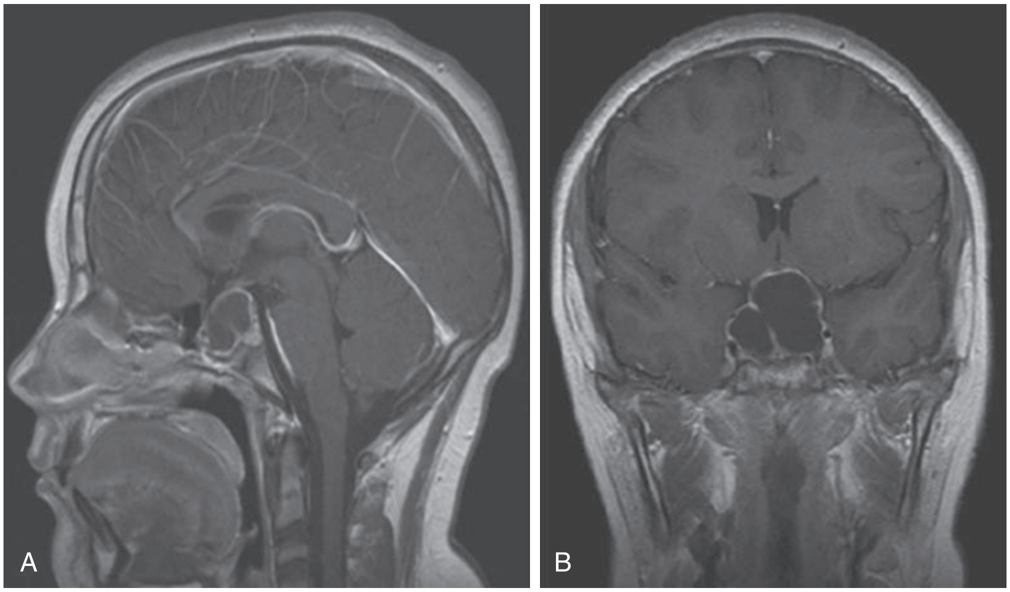

Fig. 18.5 **Magnetic resonance imaging (MRI) of cystic craniopharyngioma.** Saggital MRI scan (**A**) revealing a large, multicystic craniopharyngioma arising from the pituitary fossa and extending up to hypothalamus. Coronal section (**B**) of the same lesion delineating upward and lateral spread. Both images are T1-weighted, gadolinium-enhanced scans.

abnormal dendritic cells that can affect either a single site or many systems, causing multiorgan dysfunction. In children, the median age of diagnosis ranges between 1.8 and 3.4 years.

LCH infiltrates the HP area in 15% to 35% of patients, with subsequent development of at least one pituitary hormone deficiency.[87]

In a multicenter French national study of 589 pediatric patients with LCH, 145 patients (25%) had pituitary dysfunction. In 60 patients, pituitary involvement was already present at the time of diagnosis, and in 20 of them it was the first manifestation of the disease. Patients at high risk of pituitary involvement seem to be those with multisystem disease involving the skull and facial bones, mastoid, sinuses, and mucous membranes (i.e., gums, ear, nose, and throat region). Furthermore, compared with patients without pituitary involvement, patients with pituitary involvement have a higher rate of relapse (10% at 5 years vs. 4.8% at 5 years) and a higher incidence of neurodegenerative LCH.[88]

DI is the most frequently reported permanent consequence of LCH and the commonest endocrinopathy; almost all patients with pituitary involvement have DI. The second commonest endocrinopathy is GHD, which occurs in 14% of all patients with LCH and in more than 40% of patients who have pituitary involvement. In the vast majority of patients, GHD is associated with DI, with a median interval of 2.9 to 3.5 years between the diagnosis of DI and development of GHD. Isolated GHD, or the association of GHD with other anterior pituitary hormone deficiencies, occurs less commonly.

Pituitary MRI findings in patients with LCH include thickening of the pituitary stalk, suggestive of the infiltrative process enhancing changes in the pituitary gland and hypothalamus, and absence of the bright signal of the posterior pituitary in T1-weighted images, caused by the loss of the phospholipid-rich antidiuretic hormone secretory granules. The latter is an invariable feature of patients who develop DI.[89] Although at the time of diagnosis of DI 75% show a thickened pituitary stalk, only 24% have persistent stalk thickening after 5 years. These changes are variable and do not correlate with treatment or with clinical recovery; DI persists in all cases.

Long-term follow-up of patients with LCH has shown that the already established hormone deficiencies cannot be reversed by treatment.[89] Recently, however, isolated case reports have suggested that treatment with the purine analogue 2-chlorodeoxyadenosine (2-CDA) may reverse established DI. Subsequent studies of this form of therapy, used in refractory cases of LCH involving the CNS, showed that 2-CDA may result in partial or complete radiologic improvement of the mass lesion, but the endocrine consequences of the disease, including DI and panhypopituitarism, do not reverse.[90] Patients treated with the JLSG-96 protocol who have been followed up for 5 years developed DI with an incidence of 3.1% to 8.9%, depending on the extension of the disease (single system multisite vs. multisystem).[91]

Radiotherapy used for the treatment of LCH is within the dose range of 10 to 15 Gy, which is known to be unlikely to cause GH insensitivity. However, radiotherapy has been associated with an increased risk of GHD despite the use of a dose less than 15 Gy, a finding that may reflect the severity and extent of the disease rather than the direct effect of radiotherapy.

Irradiation of the Central Nervous System. Cranial irradiation used for the therapy of solid brain tumors and as prophylaxis for leukemia can lead to abnormal HP function. The sensitivity of the HP axis to radiation depends upon the dose, the fractionation, the tissue location, and the age of the patient.[92] Such damage is typically difficult to assess precisely, because the hypothalamus and pituitary may differ in the extent of involvement, and the loss of function may evolve with time.

Sensitivity to CNS radiation may differ among patients, although the majority of children will experience some degree of hypothalamic or pituitary dysfunction within 5 years of receiving 30 Gy. GHD also occurs with doses of 18 to 24 Gy,[93] and subtle dysfunction may be observed at even lower doses.

GH secretion generally appears to be the most sensitive to irradiation, followed by TSH, gonadotropins, and finally ACTH. This may relate to the unique position of the GHRH neurons on the surface of the hypothalamus and not deep within the structure, as previously thought.[94]

Pituitary dysfunction evolves over several years following irradiation, so such children should be monitored for growth deceleration.

Provocative GH testing may be within normal limits, but measures of spontaneous GH secretion frequently demonstrate abnormalities.

Serum concentrations of IGF1 or insulin-like growth factor-binding protein-3 (IGFBP-3) may not be reduced in the early years following cranial irradiation.[95]

Cranial irradiation may also result in precocious puberty, leading to an early pubertal growth spurt, advanced skeletal maturation, and ultimately reduced stature. This may be superimposed upon any growth restriction that results from the spinal irradiation for the primary problem.[96] Low-dose irradiation is frequently associated with a precocious onset of puberty; higher doses may result in gonadotropin deficiency and pubertal delay. In the irradiated child with early puberty, therapy with gonadotropin-releasing hormone analogs (GnRHas) should be considered, with or without GH treatment, to delay epiphyseal fusion.

Lower doses of radiation (24 Gy) are also associated with GHD in approximately 30% to 60% of cases. Craniospinal irradiation used in the treatment of posterior fossa tumors and total-body irradiation used in conditioning regimens for bone marrow transplant are also associated with damage to the epiphyses, with subsequent disproportionate short stature.

Traumatic Brain Injury. Traumatic brain injury (TBI) has been recognized as a cause of acquired hypopituitarism in a number of adult studies. Data on pediatric patients are sporadic, but TBI is probably underdiagnosed.[97]

These effects may be significant, considering the scale of the problem. In the United Kingdom, 180 children per 100,000 population per year sustain a head injury, with 5.6 per 100,000 requiring intensive care and almost one third of those admitted to the intensive care unit undergoing neurosurgery.

Although the pituitary gland is protected within the bony cavity of the sella turcica, the rich vascular network of the hypothalamus and pituitary and the structure of the pituitary stalk make it vulnerable to the effects of TBI. The hypothalamus and pituitary have a complex vascular supply consisting of an arterial supply via the superior and inferior hypophyseal arteries from the internal carotid artery, as well as long hypophyseal vessels and a rich network of portal capillaries that surround the pituitary and infundibulum. The pathophysiology of hypopituitarism related to TBI is not clearly defined, but it is thought that it is the result of direct trauma or of vascular injury resulting in ischemia and infarction,[98] an observation supported by the anatomical findings of autopsies following head trauma, which include anterior lobe necrosis, pituitary fibrosis, hemorrhage, infarction, or necrosis of the pituitary stalk.[99]

Hormone deficiencies may be identified in the first days to weeks posttrauma (acute phase) or may develop over time (late effect). Because there is overlap between the symptoms and signs of hypopituitarism and those of neurologic/psychologic sequelae of TBI, it is possible that late-evolving or partial deficiencies can remain undiagnosed for extended periods.

In the acute phase, alterations in the endocrine function may reflect an adaptive response to acute illness. The clinically significant alterations involve mainly the regulation of fluid and electrolyte balance (DI, syndrome of inappropriate secretion of antidiuretic hormone, cerebral salt wasting) and the hypothalamo-pituitary-adrenal axis. Most of the pituitary hormone changes observed in the acute phase are transient, and their development cannot predict the development of permanent hypopituitarism.[100]

Pituitary hormone deficiencies present in the acute phase are usually transient, but they may persist or appear and evolve over time. In adults, the incidence of permanent hypopituitarism ranges between 23% to 69%, depending on the study. The GH axis is the most frequently affected (10% to 33%), followed by the gonadal (8% to 23%), adrenal (5% to 23%), and thyroid (2% to 22%) axes. The prevalence of permanent DI varies between 0% and 6%. In children with a TBI diagnosis there was a 3.22 times higher risk of a subsequent central endocrine diagnosis compared with the general population (± 0.28).[101]

Until recently, there were only sporadic reports of hypopituitarism following TBI in children, but prospective studies designed to address the problem in the pediatric and adolescent population are in progress. The incidence of hypopituitarism is reported to range from 10% to 60%, and although this is lower in children as compared with adults, it is not uncommon.[102] In general, the long-term outcome of TBI seems to be more favorable in children, although quality-of-life issues and minor disability may persist. The extent to which endocrine dysfunction contributes to these outcomes has yet to be defined.

GHD appears to be the main endocrine manifestation, followed by gonadotropin deficiency. GHD can present as growth failure, whereas delayed or arrested puberty and secondary amenorrhea may present in adolescents and in patients in the transition phase. In a number of case reports, central precocious puberty has also been described in association with head injury, presenting 0.4 to 1.6 years after the event.[103]

Patients with hypopituitarism after head injury may have no clinical signs and symptoms suggestive of this disorder; its correct identification requires a high degree of suspicion. An international consensus guideline on the screening of adult patients post-TBI suggests that all patients who had TBI, regardless of its severity, should undergo baseline endocrine evaluation 3 and 12 months after the event or discharge from the intensive treatment unit.[104]

With reference to children, there are still not enough data from prospective studies to recommend a systematic approach for screening patients after TBI.[105] Even more controversial is the issue of recommending treatment with rhGH post-TBI to improve cognitive outcome and quality of life[106] or in patients with evidence of abnormal GH secretion on provocation testing who have normal growth.[105]

Infiltrative and Inflammatory Disorders. Infiltrative diseases are uncommon causes of GHD in the pediatric population, but pituitary insufficiency may be observed secondary to CNS involvement in tuberculosis, sarcoidosis, or toxoplasmosis. Inflammation associated with bacterial, viral, fungal, or parasitic disease may also result in HP dysfunction.[107] Lymphocytic hypophysitis has also been reported.[108]

A recently reported rare cause of acquired hypopituitarism in adults with GH, TSH, and PRL deficiency results from insults specific to the somatotrope cell lineage, associated with autoimmunity to Pit-1 (POU1F1), positive serum anti-Pit1 antibodies, and histologically a marked reduction of pituitary somatotropes with infiltration by lymphocytes and plasma cells.[109] It is as yet unknown if this may also be a cause of acquired GHD in children and adolescents with autoimmune disorders.

Thalassemia is a hereditary disorder characterized by quantitative defects in synthesis of globin chains that result in ineffective erythropoiesis and, in its more severe forms, transfusion dependence. The majority of complications are the consequence of the toxic effects of iron, which is deposited in organs of the reticuloendothelial system, the heart, and all target organs of the endocrine system, including the pituitary. The anterior pituitary is very sensitive to iron overload, resulting in defective GH secretion, reduced responsiveness of GH to GHRH, and hypogonadotropic hypogonadism. The gonadotrope cells seem to be particularly vulnerable to the toxic effects of iron deposition, which may be related to the way iron is transported in cells. Failure of pubertal development and growth impairment are the most prominent endocrine complications, and may occur despite early initiation of chelation therapy. It is estimated that 56% of thalassemic patients have at least one endocrinopathy; almost half have hypogonadism (40% to 59%), and 33% to 36% manifest growth failure.[110] Of

202 thalassemic patients below the age of 18 years, the reported endocrine complications included GHD in 4.5%, latent hypocortisolism in 4.4%, and central hypothyrodisim in 0.5%.[111]

The growth impairment is the result of a number of factors that include chronic anemia and tissue hypoxia, overchelation due to the toxic effects of desferrio-xamine on spinal cartilage, GH insufficiency, and possible GH insensitivity.

Vascular Lesions. Aneurysms may behave as space-occupying lesions and cause hypothalamic or pituitary destruction.[112]

Psychosocial Dwarfism. Psychosocial dwarfism is a form of poor growth associated with bizarre eating and drinking behavior, social withdrawal, delayed speech, and on occasion other evidence of developmental delay. Periodic hyperphagia is associated with decreased GH responsiveness to standard provocative stimuli but also with subnormal responses to exogenous GH therapy. Removal from the stressful environment, which usually involves removal from the home, is accompanied by a restoration of normal GH secretion, typically within weeks, and a period of catch-up growth.[113]

The mechanisms for this reversible form of GHD are unclear, but it is of note that a variety of psychiatric conditions in adults may be associated with decreased spontaneous and provocative GH secretion.

Establishing the diagnosis of psychosocial dwarfism requires documentation of catch-up growth and restoration of normal GH secretion following correction of the environmental situation.

The Hypothalamo-Pituitary-Somatotroph Axis

GH is secreted by somatotropes in the anterior pituitary gland. The secretory pattern is pulsatile, with discrete pulses of GH every 3 to 4 hours and virtually undetectable GH concentrations in between. Secretion of GH varies considerably with age and shows a sexually dimorphic pattern, with a greater average daily GH output in women. This pattern is the result of an interaction between the hypothalamic peptides GHRH and somatostatin (SS). The amplitude of the GH peak is determined by GHRH, which stimulates the pituitary somatotrophs to increase both the secretion of stored GH and GH gene transcription. SS determines trough levels of GH by inhibition of GHRH release from the hypothalamus and GH release from the pituitary. Withdrawal of SS, on the other hand, determines the timing of a GH pulse.

More recently, the use of synthetic GH-releasing peptides (GHRPs) has led to the identification of a GH secretagogue (GHS) receptor (GHS-R type 1a). The receptor is strongly expressed in the hypothalamus, but specific binding sites for GHRP have also been identified in other regions of the CNS and peripheral endocrine and nonendocrine tissues in both humans and other organisms.[114] The endogenous ligand for the GHS receptor, ghrelin, was isolated from the stomach and is an octynylated peptide consisting of 28 amino acids. It is expressed predominantly in the stomach, but lower amounts are present within the bowel, pancreas, kidney, immune system, placenta, pituitary, testis, ovary, and hypothalamus. Ghrelin not only leads to the secretion of GH but also stimulates PRL and ACTH secretion. Additionally, it influences endocrine pancreatic function and glucose metabolism, gonadal function, appetite, and behavior.[114] It can also control gastric motility and acid secretion and has cardiovascular and antiproliferative effects.[114] The role of endogenous ghrelin in normal growth during childhood remains unclear. Both ghrelin and GHRPs release GH synergistically with GHRH.[114]

The expression of the human *GH1* gene is regulated not only by a proximal promoter, but also by a locus control region (LCR) 15 to 32 kb upstream of the *GH1* gene. The LCR confers pituitary-specific, high-level expression of GH.[115] The full-length transcript from the *GH1* gene encodes a 191–amino acid, 22-kD protein that accounts for 85% to 90% of circulating GH. Alternative splicing of the mRNA transcript generates a 20-kD form of GH that accounts for the remaining 10% to 15%. Within both the proximal promoter and the LCR are located binding sites for the pituitary-specific transcription factor Pit1. Therefore, the LCR region may be considered as initial "entry" point for the recruitment of the tissue-specific Pou1f1 (Pit-1), which in turn triggers chromatin remodeling and recruitment of coactivators.[116] Additional binding sites for the transcription factor Zn15 are also located within the proximal promoter.

In the circulation, GH binds to two binding proteins, high-affinity GHBP and low-affinity GHBP.[117] Little is known about the low-affinity GHBP, which accounts for approximately 10% to 15% of GH binding, with a preference for binding to 20-kD hGH. The high-affinity GHBP is a 61-kD, glycosylated protein that represents a soluble form of the extracellular domain of the GHR that can bind to both 20- and 22-kD hGH and thereby prolong the half-life of GH. The GHR is present in a number of tissues. GH binding induces a conformation change of constitutively dimerized GHRs by rotation, activating a receptor-associated tyrosine kinase JAK2 that in turn is autophosphorylated and also phosphorylates the GHR. This then leads to signal transduction using the MAPK, STAT, and PI3 kinase pathways. The end result is activation of a number of genes that mediate the effects of GH. These include early-response genes encoding transcription factors such as c-Jun, c-Fos, and c-Myc— implicated in cell growth, proliferation, and differentiation—and IGF1, which mediates the growth-promoting effects of GH.[118] IGF1 and IGF2 are single-chain polypeptide hormones that are widely expressed. Together with a family of specific binding proteins, they are believed to mediate most of the actions of GH.[119]

KEY POINTS

- The development of the pituitary is a highly complex process dependent upon a number of genetic factors encoding transcription factors as well as signalling molecules. Mutations in several of these genes are associated with various congenital forms of GHD including syndromic and non-syndromic forms of hypopituitarism as well as isolated GHD. The inheritance, penetrance and phenotypes associated with these mutations are highly variable. Acquired forms of GHD are caused by tumours and their treatments, inflammation, infiltration, and rarely, trauma.

CLINICAL FEATURES

Neonatal Presentation

Recent studies in humans and in animal models have demonstrated marked similarities, but also critical differences, between the clinical features of GHD and various forms of IGF deficiency.[4,120] In GHD, prenatal growth is near normal, although mild reductions in birth length and weight have been observed.

GHD does not cause severe intrauterine growth restriction, whereas loss of placental GH does. However, loss of IGF1 *in utero* results in severe intrauterine growth restriction in both humans and mice, suggesting that IGF1 and the IGF1 receptor are critically involved in intrauterine growth.[121] IGF1 synthesis and secretion *in utero* are not regulated primarily by pituitary GH.

IGF1 production comes under GH regulation either in the last few months of fetal life or shortly after birth, and is well-established by 6 months of age. Growth failure is greater for skeletal growth than for body weight, so infants and young children have an appearance of relative adiposity. Neonates may present with hypoglycemia, and this suggests the possibility of other pituitary hormone deficiencies, especially ACTH. Normoglycemia is only maintained when cortisol replacement therapy is commenced, suggesting that ACTH (and consequently cortisol) secretion is critical for glucose homeostasis. However, the

GH-IGF1 axis also plays a role in maintaining glucose homeostasis, although IGHD is rarely associated with neonatal hypoglycemia. A diagnostic fast may be required to dissect CPHD from other causes of hypoglycemia, although the distinguishing feature from hyperinsulinism is the absence of ketone body formation in the latter.

The presence of concomitant gonadotropin deficiency is suggested by the presence of microphallus, cryptorchidism, and scrotal hypoplasia. Genital ambiguity would not be expected, owing to placental production of hCG. Prolonged jaundice with conjugated hyperbilirubinemia and cholestasis may also be observed, typically in patients with CPHD. The relative contributions of GH, ACTH, and TSH deficiency to this presentation are unclear. It is imperative that the diagnosis of pituitary insufficiency be considered in any infant (especially term) with hypoglycemia, cryptorchidism, and microphallus, or conjugated hyperbilirubinemia. Associated features that might indicate more widespread problems (midline defects of the face, a single central incisor, nystagmus, and/or optic nerve hypoplasia) should be looked for, and MRI undertaken.[22]

Infant And Childhood Years

After the perinatal period, the defining feature of GHD is growth failure. Reduced skeletal growth may be observed during the first 6 months of life in congenital GHD, but by 6 to 12 months of age early growth failure is almost inevitable.[3]

Height velocity is usually between –2 and –5 standard deviations (SDs) from the mean, leading to progressive height centile crossing. In patients with acquired GHD, the critical feature is a change in growth rate. Between the age of 2 years and the onset of puberty, children maintain their height percentile with remarkable integrity. Deviation from this channel (either acceleration or deceleration) needs investigation.

Thus, a child who has been growing along the 75th percentile but moves across to the 25th percentile warrants evaluation, even though his/her height may still be within the normal range.

Bone age is often delayed in patients with GHD, but this may not be so in acquired GHD. The close proximity of time to the growth failure or acquired GHD accompanied by accelerated puberty is occasionally seen in patients with intracranial tumors, when bone age may be accelerated. Delayed dentition may be observed, but in the absence of midline craniofacial abnormalities is otherwise normal. Other skeletal appearances include hypoplasia of facial bones, hypoplastic nasal bridge, frontal bossing, and delayed closure of sutures. Head circumference is usually at the lower limits of normal, indicating normal brain growth.[3,123]

An increase in adiposity, particularly central adiposity, can be detected by careful measurement of skinfold thickness. Genital growth prior to the onset of puberty is usually proportional to body size. Puberty may be delayed, but in the absence of other endocrine deficiencies is otherwise normal.

Limited data are available on the adult height of untreated GHD patients. These results are often difficult to interpret because of (1) heterogeneity in the timing of GHD, (2) heterogeneity in the severity of GHD, (3) the presence or absence of other pituitary deficiencies, and (4) delay in puberty, resulting in late epiphyseal fusion. Wit et al.[124] summarized the results from studies of 22 men and 14 women with untreated isolated GHD who underwent spontaneous puberty and reached a mean final height of 4.7 SDs (range 3.9–6.0) below the population mean.

DIAGNOSIS OF GROWTH HORMONE DEFICIENCY IN CHILDHOOD

The diagnostic evaluation of children with growth failure is complex, because there are multiple causes for short stature (Table 18.4). In the pursuit of the diagnosis of GHD, other causes for short stature need to be considered and excluded. This is because the diagnosis of GHD is a multistep process that requires meticulous evaluation of the clinical history, auxology, and biochemical data, with increasing contribution from pituitary MRI and results of genetic studies.[125] GH is the final common pathway for postnatal growth, and many causes of poor growth may secondarily affect GH secretion. There are a number of tests available for assessing GH status.[126] Considerable attention has been paid to the underlying mechanisms assessed by the tests, how the samples should be collected, and what type of measurement should be performed. Less attention has been paid to the statistical assumptions underlying the performance of diagnostic tests. The statistical theory behind many tests is complex, because the results do not follow an all-or-none law. Rather than being left with a clear-cut answer to the initial diagnostic question, the clinician is more likely to be left with a series of probabilities as to whether or not the patient is likely to have GHD.

TABLE 18.4 **Causes of Short Stature**

Nonpathogenic
Constitutional delay of growth and puberty
Familial short stature
Nutritional
Low Birth Weight
Systemic Disorders
Cardiovascular disease (e.g., congenital heart disease)
Renal (e.g., chronic renal failure, renal tubular disease)
Respiratory (e.g., cystic fibrosis, asthma)
Gastrointestinal disease (e.g., Crohn disease)
Neurologic (e.g., brain tumor)
Psychologic (e.g., anorexia nervosa, child abuse)
Endocrine Causes
GH (growth hormone)-related causes
GH deficiency: isolated or combined with other hormone deficiencies
Resistance to GH
Insulin-like growth factor-1 deficiency
Hypothyroidism
Pseudohypoparathyroidism
Glucocorticoid excess
Cushing syndrome
Congenital adrenal hyperplasia
Exogenous administration
Genetic Causes
Turner syndrome
Noonan syndrome
Down syndrome
Skeletal dysplasias: hypochondroplasia, achondroplasia, spondylo-epiphyseal dysplasia
Russell–Silver syndrome
Seckel syndrome
Prader–Willi syndrome
Miscellaneous other syndromes (e.g., Rothmund–Thompson syndrome, Leri–Weill syndrome, progeria, mucopolysaccharidoses)

Guidance Derived From Clinical Assessment

Neonatal Period. Several pointers to the diagnosis of GHD have already been considered in this discussion, but in the neonatal period GHD may be isolated or associated with other pituitary hormone deficiencies. Small genitalia may point to associated gonadotropin deficiency. Hypoglycemia in the newborn period is often a feature of ACTH deficiency, although, on an arbitrary basis, a serum GH of less than 10 ng/mL is considered consistent with a diagnosis of GHD under these circumstances. This is not universal, however, and caution needs to be exercised in interpreting the GH response to hypoglycemia under different circumstances.[127] Recently, Binder et al. reported that, using a highly sensitive hGH enzyme-linked immunosorbent assay, the median GH concentration in dry blood spot samples of healthy neonates was 16.4 µg/L, while the median serum GH concentration of nine newborns diagnosed with hypopituitarism was 2.1 µg/L (maximum 5.5 µg/L), with no significant overlap between the groups. Based on these groups, the authors concluded that a single cutoff value of 7 µg/L, when measured with the same assay, would have high sensitivity (100%) and specificity (98%) for the diagnosis of neonatal GHD.[128]

Prolonged neonatal jaundice raises the question of thyroxine (unconjugated) or cortisol (conjugated hyperbilirubinemia) deficiency. Given these features, it might be possible on the basis of pattern recognition to ascribe the diagnosis of GHD to a patient with a high degree of certainty. MRI of the brain should be obtained to look for an undescended posterior pituitary, anterior pituitary hypoplasia, hypoplasia or absence of the pituitary stalk, hypoplasia of the optic chiasm, and absence or hypoplasia of the corpus callosum and septum pellucidum.[129]

Infancy and Childhood. Diagnostic evaluation in children must be based upon auxology. Although there are a number of clinical features of GHD that are said to be classic, none is specific. For example, obesity is listed as a clinical feature of GHD, but if we simply restricted biochemical evaluation to patients with obesity as the main feature, testing the GH axis would yield a large number of individuals with a poor GH response, because obesity *per se* is associated with blunted GH responses to various stimuli. Individuals who exhibit GHD are often obese, but the converse is clearly not the case.

Little is known of the sensitivity and specificity of many of the clinical observations, either alone or in combination. The prevalence of many of the clinical features within the general population is unknown, which heightens the problem. Even the presence of specific features or a combination of features will only slightly increase the likelihood of disease if they are relatively insensitive.

The manifestation of GHD as a result of a *GH* gene deletion is early, and poor growth can be detected as early as the sixth month of postnatal life. With advancing age, more GH has to be secreted to maintain concentrations of GH sufficient for growth, so idiopathic isolated pituitary GHD may present at any time. It is the degree of deficiency that dictates when the individual comes to medical attention. Table 18.5 provides general clinical rules that are a useful aid when selecting patients for further study of the GH axis.

Principles of Testing

The aim of any diagnostic test is to progress the clinical history and examination to the point where patient care is altered. No test will ever benefit a patient. It is only when subsequent treatment has to differ depending on the test result that patients will be better off. There is a vast and bewildering body of literature on GH testing, but the clinician can be guided by asking the questions detailed in Table 18.6. It is important to remember that a diagnostic test is not just about whether a disease is present or not; it may also be important in determining severity and prognosis and responsiveness to and monitoring of therapy, and as a screening tool. As such, how the test performs under one circumstance may not be the same in another. Measuring serum IGF1 concentrations may be unhelpful in screening for GHD but may be excellent as a marker of response to therapy.

TABLE 18.5 Clinical Indicators for Further Evaluation of the Growth Hormone Axis[204]

1. Height SDS below −2. Although WHO growth charts can be utilized for children up to 2 years of age, local growth charts, when available, are more appropriate for older children.
2. Height that clearly deviates from the familial background.
3. A significant decrease in height SDS (i.e., a deflection of at least 0.3 SDS/year that is not explained by the normal channeling in infancy to adjust linear growth to target height trajectory, by the prepubertal growth dip or by pubertal delay).
4. Predisposing condition (tumor, radiation, etc.) or features suggestive of an underlying syndrome.
5. Neonatal signs consistent with pituitary hormone deficiencies.

SDS, Standard deviation score; *WHO,* World Health Organization.

TABLE 18.6 Underlying Principles of Assessing Tests

1. Has there been an independent blind comparison with the diagnostic “gold standard”?
2. Was the test conducted in a wide range of patients with and without the condition?
3. Is the test reproducible?
4. What was the definition of “normal” in the test situation?
5. How might the test interact with others in a diagnostic sequence?
6. Does the test entail risk or reduce risk for the patient?

Two points deserve special mention. First, it is unusual in endocrinology for there to be a diagnostic “gold standard.” The anterior pituitary is not accessible, and molecular biology is not sufficiently advanced to give definitive answers. Second, care needs to be taken in ascribing the role of a gold standard. It may change with time, and the test must be well validated by application to large numbers of individuals with and without the condition. The temptation is to use the extremes, but this may lead to a considerable overestimate of sensitivity and specificity, which may not be borne out in field studies.[130]

Two principles operate when using diagnostic tests.[131] First, probability is a useful marker of diagnostic uncertainty. This is when the sensitivity (ability to detect a target disorder when present or true positive rate) and specificity (ability to identify correctly the absence of the disorder or true negative rate) become important. If both were 85%, 15% of patients with disease would have a negative result (false negative), and 15% without disease would have a positive result (false positive). Abnormal results would occur in patients with and without disease. Whatever the result, new information has been generated that may or may not influence decision-making. Second, diagnostic tests should be obtained only when they can alter the management of the case—that is, if the test result alters the probability of the disease.

Pre- and Posttest Probability. The relationship between the probability of disease after the results of diagnostic tests are known (the posttest probability), and pretest probability of disease depends on the sensitivity and specificity of the test, as shown in Fig. 18.6. There are two important points to note: the first is that the more certain the clinician is of the diagnosis before the test is performed, the less effect the confirmatory test has on the probability of disease. The obverse is also true. The second point is that tests will have major effects on probability of disease in the intermediate zone. Testing is not likely to be beneficial if the pretest probability is very high or low. This is one reason why screening for GH problems in short children on the basis

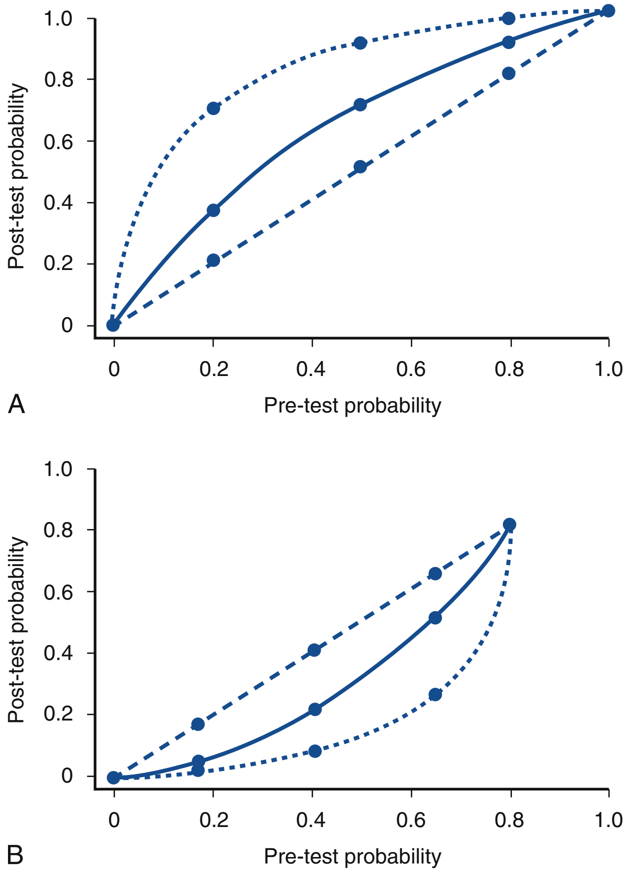

Fig. 18.6 The relation between pretest and posttest probability of disease. The data were constructed by using Bayes' theorem with a test sensitivity and specificity of either 70% *(solid line)* or 90% *(dashed line)*. **A**, The posttest probability if the test were positive. **B**, The posttest probability if the test were negative. If the posttest probability were the same as the pretest probability, then the relation would be given by the line of identity. (Reproduced from Brook CGD, Hindmarsh PC, Jacobs HS, eds. *Clinical Pediatric Endocrinology*. 4th ed. London: Blackwell Publishers, 2001.)

of biochemical tests is unhelpful; the pretest probability is 1 in 3000, or 0.03%.

Clinicians are often faced with the situation where they feel really sure the patient has the condition, but the test does not confirm this. Table 18.7 analyzes this concept. Here, specificity and sensitivity have been fixed, and the effects on posttest probability are considered. In the situation where there is a 90% pretest probability that the patient has GHD, then even if the test is negative in the individual, there is still a 67% probability (reduced by 23%) that they have the condition, so treatment would still be justified. When the pretest probability was 5% (very certain that the patient does not have GHD) and the test is positive, all the result says is that the patient has a 1 in 4 chance of having the condition, so we would probably not treat. In the middle ground, certainty in either direction is dramatically improved.

Multiple Tests. Table 18.7 could have been made much larger by introducing any number of pretreatment probabilities. There comes a point, however, when posttest probability changes to a level where a decision has to be made to stop and either accept or reject the proposal that the condition is present. The decision to stop investigation and to treat or not depends on how convinced the clinician is of the diagnosis, the benefits and risks of the therapy, and the potential yield and risks of further tests. There are two ways to assist this situation: conduct another test or use a more sophisticated analysis rather than a simple positive or negative.

TABLE 18.7 Effect on Posttest Probability of Differing Pretest Certainty, Assuming Constant Sensitivity and Specificity

	POSTTEST PROBABILITY	
Pretest Probability (%)	**Test Positive**	**Test Negative**
90	98 (+8)	67 (–23)
50	87 (+37)	19 (–31)
5	25 (+20)	1 (–4)

Change from pretest probability in parenthesis.

This is problematic in the GH field, because the methodology assumes that the results of the two tests are independent. In normal individuals undergoing repeat GHRH tests, dependence cannot be assumed.[132] Where repeat tests have been performed in children, concordance was observed 50% of the time, a value close to that calculated for independent events using a test with 70% to 85% efficiency. If all tests are treated as independent, there is a risk of over- or underestimating the presence of the condition. Another important issue is whether the test may change in individuals as they age. There is evidence that the clonidine test is less effective in releasing GH in young adults compared with children. Whether the magnitude of the response to other stimuli can be assumed to remain unchanged is unknown.

Assuming that the two tests are performed (on different days) and that they are dependent, then if both tests need to be positive for diagnosis, this maximizes specificity and avoids falsely labeling normal children, but it misses many treatable individuals. Insisting that both tests are negative maximizes sensitivity and minimizes misdiagnoses, but falsely labels many more normal child.

These challenges in the diagnosis of childhood GHD are highlighted by studies showing that up to 85% (28/33) of short prepubertal children who were diagnosed with GHD based on a peak GH of less than 10 μg/L in two provocation tests had a normal GH response when retested 1 to 6 months later.[133] In other series, almost 60% to 85% of patients diagnosed with GHD in childhood had an adequate GH secretion when retested in late adolescence or adulthood.[134]

Diagnosis of Growth Hormone Deficiency

Assessment of GH secretion is problematic, in part because of the pulsatile nature of GH secretion. The most consistent GH surges accompany slow-wave electroencephalographic rhythms during phases 3 and 4 of sleep. Although this rhythmicity is characteristic of GH secretion at all ages, the size of the amplitudes and the total integrated GH secretion varies with sex, age, pubertal status, and nutrition.[135] Between pulses, serum GH concentrations are extremely low, often less than 0.1 ng/mL. Consequently, measurement of random serum GH concentrations is of no value in the diagnosis of GHD. Measurement of spontaneous GH secretion requires multiple sampling, typically every 15 minutes over a 12- to 24-hour period. Such methodologies are inconvenient and expensive, and, while they allow identification of the patient with severe GHD, it is not clear that they can discriminate between partial GHD and normal secretory variation.[136] However, even the reproducibility of GH secretory patterns in children from day to day is uncertain. Rose and colleagues[136] reported that measurement of spontaneous GH secretion identified only 57% of children diagnosed as GHD by provocative testing. Lanes[137] reported that approximately 25% of normally growing children have low overnight GH concentrations. A longitudinal study of GH secretion in normal

TABLE 18.8 Growth Hormone Stimulation Tests

Stimulus	Dose	Sampling Protocol (min)	Notes
Exercise	Cycle for 10–15 min	15 min for 90 min	Variable response, highly dependent on degree of exercise
Levodopa	<15 kg, 125 mg 15–30 kg, 250 mg >30 kg, 500 mg	15 min for 90 min	Nausea
Clonidine	0.15 mg/m^2	30 min for 90 min	Tiredness; postural hypotension
Arginine HCl	0.5 g/kg (max, 30 g) IV given as 10% arginine HCl in 0.9% NaCl over 30 min	15 min for 90 min	May cause insulin release
Insulin	0.05–0.1 units/kg IV	15 min for 120 min	Hypoglycemia; requires supervision. Can also measure cortisol reliably
Glucagon	0.1 mg/kg IM (max, 1 mg)	30 min for 180 min	Nausea
GHRH	1 μg/kg IV	15 min for 120 min	Flushing. Only assesses pituitary reserve, not whole HP axis
GHRH-arginine			Needs further work to assess value in pediatrics
Tests should be performed after an overnight fast.			
Patients should be documented to be euthyroid.			
Prepubertal children should be primed with gonadal steroids.			

GHRH, Growth hormone-releasing hormone; IM, intramuscular; IV, intravenous.

boys during puberty indicated wide intersubject variation, and day-to-day variation has been noted among normal subjects. An alternative approach has been the measurement of urinary GH concentrations.[138] This methodology requires a timed urinary collection and a GH assay of high sensitivity, because urinary GH concentrations are low. The theoretical advantages of this approach include its relative ease of performance and noninvasive nature, as well as the requirement for only a single GH measurement. This must be balanced, however, by the need to assess the effects of renal function, the wide interindividual variation, and the lack of adequate age- and sex-related reference ranges.

Obesity is another aspect that complicates primary GHD diagnosis, as visceral obesity *per se* results in a *secondary* reduction in serum GH concentrations.[139] The reasons for the hyposomatotropinism in obesity and its mechanisms have yet to be clarified.

Reductions in spontaneous GH secretion (as much as 6% for each unit increase in body mass index [BMI]) and in the half-life of circulating GH have been reported. The GH response to pharmacological and physiological stimuli is impaired in obesity.[140]

Some of the theories on the cause of altered GH physiology in obesity involve the increased concentrations of leptin, insulin, free fatty acids, and IGF1.

As a result of these difficulties, the standard for the diagnosis of GHD has been provocative testing of GH "secretory reserve" (Table 18.8). Physiologic stimuli for such tests have included sleep and exercise, and pharmacologic stimuli have included a wide variety of agents.[141] None of these tests truly mimics normal GH secretory physiology, and none has been evaluated adequately in normal children and normal short children. The limitations of provocative GH testing in the diagnosis of GHD are described below and need to be considered in the light of statistical theory (see earlier):

1. Provocative testing by its nature is nonphysiologic. None of the commonly used stimuli truly mimics normal regulation of GH secretion.
2. The definition of a "normal" response to stimulation is arbitrary. Normal values are difficult to obtain in pediatric practice, and reference ranges would be needed for tall, normal, and short children, because their GH secretion differs. In addition, both age and pubertal stage influence GH secretion, as does body composition.[142] Values for these would also have to be included.
3. The classic approach of defining normal data in terms of a Gaussian distribution does not come without hazard. Endocrine testing rarely fits this distribution; even if it did, it would imply that the lowest and highest 2.5% of values are abnormal, and that all diseases have the same frequency—clearly unlikely. Creating upper and lower limits does not help either. It is more appropriate to identify a range of diagnostic test results, beyond which GHD is likely.
4. Most decisions on placing the value have been empirical rather than statistical. In practice, cutoff values could be chosen at an absolute extreme. If 100 short children were studied, and GH sufficiency or deficiency was defined by a peak response of less than 3 ng/mL, only 3% to 5% might have a response at this level. When testing the next 100 children, one or two normal individuals might have such a response. They will be outliers, but they are important, because the more patients studied, the greater the chance of finding outliers.
5. Moving the cutoff to more extreme values to exclude these patients restricts the population of treatable individuals. Relaxing the criteria interposes normal individuals into the diagnosis zone. Placing the cutoff is based partly on clinical judgment. Because there is no perceived disadvantage apart from financial cost in falsely labeling someone with GHD and treating him or her, a relaxed cutoff would be acceptable. However, this could lead to some children receiving unnecessary treatment with GH, which is not completely without side effects.
6. The question of cutoff points for use in tests becomes more important as individuals with differing severities of the disorder are considered. In constructing normal ranges, it is clearly best if large sample sizes are chosen. Choosing populations of disease-positive and disease-negative is unwise, either for this task or assessing test performance, because it is unlikely that the test will perform as well in the less severe cases.[143] Some useful points in the assessment of studies are outlined in Table 18.9. Referral bias remains a major issue in many studies. In studies emanating from referral centers, the strength of a factor such as short stature may appear to be less important, in that patients are already selected for this in the referral. Changes in the prevalence of a condition do not change test properties, whereas changes in the spectrum of the disorder do.[144]
7. The dependence of GH secretion on other factors needs to be taken into account. Marin and colleagues[145] demonstrated that, when exercise and arginine stimulation tests were performed on normal-stature children without sex steroid priming, the lower-limits-of-normal (–2 SD) peak serum GH concentration for

TABLE 18.9 Considerations to Give to Test and Control Populations

1. What is the population from which patients are drawn?
2. How have patients been filtered before joining the study?
3. Test properties may differ in subpopulations within the sample.
4. Recruit consecutive patients with the problem.
5. Can the findings be generalized?

prepubertal children was as low as 1.9 ng/mL and rose to 7.2 ng/mL on estrogen priming. Thyroxine and cortisol, which directly alter gene transcription, influence the results obtained, and these need to be controlled before undertaking a diagnostic study. Similarly, the presence of high concentrations of glucose or free fatty acids may influence the response obtained.

8. GH assays may measure a variety of immunoreactive molecular forms of GH, and individual standards need to be established for each laboratory. These should take into account factors intrinsic to the assay used, the heterogeneity of the GH molecule (different isoforms circulating in hetero- and homodimers), circulating GHBP, and the standard preparation used for calibration. At the time of the 2000 *Consensus of the GH Research Society* on the diagnosis of GHD in children,[125] the international standard (IS) available was the IS 88/624 (recombinant 22-kDa GH). Since then, it has been replaced by the IS 98/574, the implementation of which has been recommended by an international consensus statement on the standardization and evaluation of GH and IGF assays.[146] These recommendations and the current use of monoclonal assays make it imperative to review the accepted GH cutoff used for diagnosis of GHD in children. Assay precision, accuracy, and sensitivity play an important role in determining the success or failure of the diagnostic test. For example, assays for IGF1— despite having good standardization from the technical aspect (elimination of interference of IGFBPs and the use of high-affinity, high-specificity antisera)—may have different performance characteristics when concentrations are either above or below the normal range.[147]
9. Most endocrine tests are conducted over short periods of time, and results are extrapolated to longer time frames. GH provocation tests take 2 hours to perform, and the results are then compared with height velocity measurements obtained over a longer period of time, often 1 year. That there is a relationship is perhaps surprising; that there are high false-positive and false-negative rates is probably not.
10. Hormone pulsatility may also influence diagnostic tests if the test itself is influenced by oscillations (e.g., the stimulus applied) within the system under study. The GH response at any point in time is going to be heavily dependent on the interplay between the hypothalamic regulatory peptides involved in GH release, namely GHRH and SS. SS, in particular, is a key determinant of the amount of GH released as a result of GHRH stimulation. Attempts have been made to take control of this variable by the use of GHRH combined with arginine.[148] An alternative approach is the use of ghrelin.[149] However, in patients with congenital hypopituitarism the GH response to ghrelin depends on the degree of the anatomical abnormalities, as the main action of the peptide is at the hypothalamic level and requires the integrity of hypothalamic–pituitary connections.[150]
11. Endocrine systems are also subject to feedback from target tissues, and this is an issue not only in the interpretation of single provocation tests, but also where second tests are performed in rapid succession to the first. A diminished response to GHRH can be observed if the second stimulus is applied 1, 2, or 3 hours after the first. The implication of doing two tests on the same day, often following each other, are immense; the cutoff that might be implied to determine normality or not may not be the same for the second test as for the first, especially if the second stimulus is different from the first.
12. Provocative testing fails to give any consideration to the effect of negative feedback by serum IGF1. It probably makes more sense to interpret serum GH concentrations in the light of serum IGF concentrations, much as TSH concentrations are best assessed with a knowledge of circulating thyroxine concentrations.
13. In assessing the results of endocrine evaluations, it is generally assumed that the single or multiple samples measured are relatively stable, at least over short periods. When important changes are postulated to be taking place, for example in a disease process, some knowledge of the inherent variability within the measurement system is required. In the short term, a number of studies have demonstrated variability within and between individuals in terms of GH tests. Group data are usually reproducible, but problems can arise if it is assumed that individual oscillatory profiles are consistent from day to day.
14. In considering provocative tests, the situation may arise where no response is observed. A possible explanation is that the strength of the stimulus was insufficient to provoke hormone release. In such a situation, it is valuable to have an independent marker of stimulus application. In the insulin-induced hypoglycemia test, this marker is glucose and the attainment of adequate hypoglycemia. In the glucagon test, it may be the release of glucose. In other tests, there may be no independent markers, so doubt may be cast on the reliability of the nonresponse.
15. Careful consideration needs to be given to the age of the child under study. Not only may the cutoff point criteria differ at different ages, but the likelihood of disease presence will change with age. It is highly unlikely that GHD will manifest itself during puberty. It is possible, but it is more likely that any growth or GH secretory problems at this age relate more to delayed puberty rather than an abnormality in the GH axis. Even in childhood, the return in terms of diagnosis of GHD is not high if height screening is undertaken at school entry, so that with increasing age there is a diminishing diagnostic return.
16. Provocative GH testing is expensive and uncomfortable, and has risk. Insulin-induced hypoglycemia should only be performed in a supervised setting. Deaths have been documented in patients rendered hypoglycemic and corrected in an overly vigorous manner.
17. Of the provocative tests listed in Table 18.8, it should be noted that stimulation with GHRH is not designed to document whether a patient has GHD, but rather whether GHD, established by other methodologies, is the result of pituitary or hypothalamic dysfunction. Failure to respond to GHRH suggests that the abnormality is at the pituitary level. This test may be enhanced by the addition of arginine or pyridostigmine.

A Practical Approach to Diagnostic Evaluation

A practical approach to the diagnosis of a child with GHD is grounded on clinical assessment with allocation of pretest probability of disease presence. In the neonate and first few months of life, Binder and colleagues[151] proposed a GH cutoff of 7 μg/L, while most recent guidelines have suggested that a cutoff of 5 μg/L in a newborn with additional pituitary hormone deficiencies and/or structural abnormalities of the pituitary is more appropriate.[152] In the prepubertal child with abnormal growth, serum concentrations of IGF1, IGFBP3, and/or ALS provide a means for excluding a diagnosis of GHD. Provocative GH testing with appropriate sex steroid priming will provide information on GH secretory capability, and GHRH stimulation, with or without arginine or pyridostigmine, will allow determination of whether the defect is at the hypothalamic or pituitary level.

All data need to be interpreted together with known test performances and integrated with the pretest probability to generate a posttest probability that would then lead to a decision as to whether intervention is required.

The interpretation of second tests of GH secretion may be problematic from both the physiologic and statistical standpoints, and should be analyzed with extreme caution.

Documentation of GHD also requires that other pituitary functions be assessed periodically, including TSH, ACTH, and gonadotropin status. Other pituitary deficiencies may not be evident upon initial assessment but may develop over time. MRI of the hypothalamus and pituitary should be performed initially to determine if there is evidence of intracranial tumors, pituitary hypoplasia or PSIS, or midline defects. Even if the baseline MRI is normal, in the absence of an alternative explanation for GHD or CPHD, the possibility of tumors or structural defects should not be dismissed permanently. With increasing knowledge of the genetics of pituitary disorders, these should be looked for, because they have an impact on the likelihood of other pituitary hormone deficiencies evolving with time and allow genetic counseling to be undertaken.

KEY POINTS

- The diagnosis of GHD is by no means simple, and often involves careful evaluation of the clinical history, examination, basal biochemistry, GH response to stimulation, radiology including a bone age and MRI of the brain and pituitary, and molecular analysis. Confounding factors in the interpretation of GH responses to provocation include obesity.

TREATMENT

Growth Hormone

The first successful treatment of human GHD with hGH was in the 1950s, while rhGH became available in 1985. This allowed for potentially unlimited supplies, obviating the need for low-dose usage and interrupted therapeutic regimens. The initial rhGH preparation was an N-terminal methionine, met-rhGH, which was fully active biologically but was ultimately replaced by the mature 191–amino acid protein. Since then, information on the safety of rhGH treatment has mainly been obtained from large postmarketing databases including patients with GHD of variable etiology and non-GHD subjects, confirming an overall safe profile.[153,154]

Dose Studies. Investigations of optimal dosing of rhGH have been complicated by the use of heterogeneous study populations, as studies frequently include patients with unequivocal and complete GHD together with patients with partial GHD. Therefore, it is not surprising that, despite long experience in the use of rhGH, there still remains uncertainty regarding the best dosing regimen, its calculation based either on weight or surface area, and a satisfactory way to quantify and predict responsiveness to treatment. It is generally accepted that a daily dose of 0.025 to 0.035mg/kg/day is sufficient to increase growth velocity to more than 10 cm/year in children with severe GHD and the adult height in treated patients ranges from –1.5 to –0.8 SDS, depending on the study.[155,156] Several studies have demonstrated a dose-response relationship for hGH, but the slope of the response is relatively shallow. Cohen et al.[157] compared the growth responses of prepubertal, naive patients randomized to rhGH at a dosage of 0.175, 0.35, or 0.7 mg/kg/week for the first 2 years of treatment. Significantly greater height velocities and gains in height SD resulted from the 0.35 mg/kg/week versus 0.175 mg/kg/week, but no further significant improvement was observed with the 0.7-mg/kg/week dosage. Ultimately, the issues that should determine dosage in the child with GHD are (1) how best to return the GHD child to the normal growth curve, (2) how best to ensure that the child attains his or her genetic height potential, (3) risks, and (4) cost.

However, instead of fixed dose regimens, titration of the dose of rhGH according to a target IGF1 SDS near the age- and gender-adjusted mean (IGF1 SDS of −0.5 to +0.5) seems to be beneficial in terms of growth, at least in the short term, with great variability in the dose required.[178] Although dose titration to achieve higher IGF1 targets (IGF1 SDS of +1.5 to +2.5) resulted in a higher growth response over a 2-year term, it is not possible to conclude that this dosing strategy will result in improved adult height outcome.[158]

Response to GH therapy varies even when the diagnosis is homogeneous. This probably reflects differences in tissue responsivity, which may relate in part to the function of the GHR. A polymorphism in the *GHR* gene leading to retention (full-length) or deletion of exon 3 (d3), which encodes a 22–amino acid sequence in the extracellular domain,[159] has been associated with a greater height increase in response to GH replacement in children born small for gestational age (SGA), those with idiopathic short stature (ISS),[160] and in a GHD population.[161] Patients with at least one d3 allele had a significantly better first-year response leading to an improved adult height on GH treatment than patients with homozygosity for full-length GHR. However, not all reported studies are consistent, which may reflect differing populations and conditions.[162] In the current context, the use of the GHR polymorphism, alone or in association with other genetic variants within the GH-IGF1 axis, is of little value in prediction models to estimate the response to rhGH treatment in short children.[163]

False-positive findings are more likely with small sample sizes, and for quantitative trait loci, phenotypic variations tend to be overestimated with small sample sizes.

Frequency of Administration. Several studies have compared the short-term effects of administering hGH either daily or thrice weekly. Generally, daily injections are more effective, but increasing the frequency more than this makes little difference.

Multiple long-acting growth hormone (LAGH) preparations are currently at various stages of development, allowing for decreased GH injection frequency from daily to weekly, biweekly, or monthly, and thus improved adherence.[164,165]

Longer-acting agents (LAGHs) can be divided broadly into depot formulations, PEGylated formulations, prodrug formulations, noncovalent albumin-binding GH, and GH fusion proteins. Following administration of LAGH, the serum peak and trough GH and IGF1 concentrations vary depending upon the mechanism used to prolong GH action. Randomized, controlled clinical trials have not reported significant LAGH-related adverse events during short-term therapy. In order for LAGH to replace daily rhGH in the treatment of GHD, further studies are needed to clarify methods of dose adjustment, timing of monitoring of IGF1, safety, efficacy, and cost-effectiveness. Furthermore, long-term surveillance registries to evaluate efficacy and safety will be essential for understanding the impact of prolonged exposure to these compounds.[166]

Prediction Models. A series of models have been derived[167] that describe factors that may influence response, but none has gone on to be tested in formal randomized controlled trials. Further problems arise when large multicontributor databases are used, because of the

TABLE 18.10 Specific Issues with Prediction Models of Response to Growth Hormone Treatment Development

1. Regression to the mean
2. Prediction gives average effect; how to apply to individuals for prognosis
3. Predictors may not be independent of each other; assumptions made in linear and multiple regression modeling
4. Assumptions about uniformity of response
5. Spurious correlations involving time

accuracy of the data entered; when prognosis is considered, factors that may be important may not have been recorded. It has been reported that, in children with GHD, auxologic parameters such as chronologic age (the younger the patient, the better the response) and the difference between target height and actual height (the smaller the patient, the better the response) are better predictors of growth response than the cumulative weekly GH dosage. There are several problems with these types of models:

1. Although prediction models are useful to give an average effect,[168] they are not individualizable. These models explain only approximately 40% to 60% of the observed variability and are limited by their short-term endpoints, the lack of validation in long-term randomized trials, and the fact that they do not take into account the genetic makeup of the individual.
2. They often only focus on one outcome, usually short-term growth, whereas interest may be more centered on final height. The two need not necessarily be related, and the factors that influence response in the first year of treatment may differ totally from those that lead to prediction of the individual's final height.
3. Very few prediction models have been constructed from an *a priori* hypothesis, and care needs to be taken that there has been no interference from other factors accompanying the disease that might affect prognosis.
4. Rules derived from one data set may reflect associations that have occurred by chance and often result from overfitting of the data.
5. There is always the possibility that the predictors are idiosyncratic to the population, to the setting, to the clinicians, or to other aspects of the original study. Specific issues associated with growth-response models are summarized in Table 18.10.

Height and Other Outcomes. Early initiation of therapy, combined with careful attention to dosage adjustments and compliance, is the best predictor of cumulative growth response in patients with GHD. Final height correlates with height at the initiation of puberty, so it is important to maximize growth during the prepubertal period, within the limits of safety and economy. Analysis of data on final heights of rhGH-treated GHD is complicated by the heterogeneity of patient groups and dosage. In earlier reports a common observation was a general failure of children to reach their full genetic height potential, especially in the case of IGHD and particularly in females. Price and Ranke[69] reported final heights of –1.26 SD and –1.45 SD from the mean in males and females, respectively, with IGHD, and –0.22 SD and –0.52 SD from the mean in males and females, respectively, with CPHD. In patients with longer durations of treatment and higher dosages of rhGH, adult heights tended to be greater, although they still failed to achieve full genetic height potential. Recent reports of the final height of GHD children treated with rhGH show that, as a group, they achieve a normal final height within their genetic potential,[155] although there is still considerable variability in the response depending on the population, sex, and underlying diagnosis (IGHD compared with CPHD).[154,170] Males of European/North American and Japanese origins with IGHD achieved a near-adult height of –0.8 SDS, while females achieved a height of –1.0 SDS; differences between near-adult height and midparental height ranged between –0.6 and +0.2 SDS.[155]

The timing of GH treatment initiation increases the chance to achieve near-adult height. The NordiNet International Outcome Study, a noninterventional, multicenter study, identified that near-adult height SDS achieved by patients starting treatment early (n = 40 [boys, 70.0%)]; least squares mean [standard error] −0.76 [0.14]) exceeded that achieved by those starting later (intermediate, n = 42 [boys, 57.1%]; −1.14 (0.15); late, n = 90 [boys, 68.9%]; −1.21 [0.10]).

The study concluded that early initiation of GH treatment in children with isolated GHD improves their chance of achieving their genetic height potential.[171]

It is clear that the timing of puberty has a significant impact on adult height of individuals with rhGH-treated GHD. The duration of rhGH treatment and the height gained prepubertally are typically greater when puberty is induced rather than spontaneous. Final heights were greater after induced puberty compared with spontaneous puberty in boys (171.3 vs. 166.0 cm) and in girls (157.0 vs. 155.0 cm). Therapy designed to delay the onset of puberty (both normal and precocious) may augment the cumulative growth response to rhGH, but this is not accepted practice, and should only be considered in exceptional cases.

Final height gain can be particularly variable in children who have had treatment for malignancies. GHD is often complicated by skeletal damage following TBI or craniospinal irradiation, early puberty, hypothyroidism, gonadotropin deficiency, malnutrition, and concomitant chemotherapy. GnRHa therapy to arrest early puberty has been used in conjunction with GH treatment in this group of patients, with encouraging results. The use of GnRHa reduces the concentration of sex steroid, with a consequent delay in epiphyseal fusion. However, GH and GnRHa combination therapy in children with GHD is not widely used at present, and the long-term beneficial effects in terms of adult height are not well established.[172] It may be beneficial under certain circumstances—for example, where the diagnosis of GHD has been delayed. The effects of GnRHa in the long term are unknown, particularly on bone health; and the cost of this combination therapy would need to be weighed against the presumed benefit.[172]

Although considerable attention has been paid to growth, there is now recognition that the beneficial effects of rhGH in children extend beyond height. GH treatment in childhood can also normalize body composition, with a reduction in body fat, although effects on lean body mass are less evident.[173] It is also associated with reversible insulin insensitivity[154] and an increase in the ratio of high-density lipoprotein (HDL) to total cholesterol, improved cardiac function, and reduction of proinflammatory cytokines, along with an increase in glomerular filtration rate and acceleration of bone remodeling, with an increase in bone mineral mass.[174]

An increasing number of studies have focused on the role of GH in memory and neurocognition.[175] On the other hand, functional MRI has shown that, although children with IGHD do not have a global reduction in brain volume, specific structures are affected, with significantly lower volumes of the splenium of the corpus callosum ($P <$ 0.02), right pallidum ($P < 0.007$), right hippocampus ($P < 0.01$), and left thalamus ($P < 0.01$) compared with controls, while the development of the corticospinal tract is also affected.[176] They also exhibit specific impairments in cognition and motor skill function.[176] Well-designed studies assessing cognitive function and using advanced MRI are needed in order to clarify whether treatment with rhGH can reverse these effects and affect the neurocognitive outcome and development of GHD children.

Adverse Effects of Human Growth Hormone. Treatment with rhGH has had an excellent safety record.[153],[154] Reports of anti-GH antibodies in patients receiving rhGH have been few, with no untoward effect on the growth response. Fluid retention and carpal tunnel syndrome are observed in adults but are seldom significant in children. Whereas the incidence of type 1 diabetes mellitus is not higher in patients with idiopathic GHD than in the general population, the incidence of type 2 diabetes mellitus (T2D) is greater in those patients treated with GH, although this tends to be in those predisposed to developing the condition.[154] Idiopathic intracranial hypertension (pseudotumor cerebri) has been observed occasionally but resolves with cessation of treatment and then a gradual reintroduction of rhGH commencing at a lower dose. Slipped capital femoral epiphysis has been reported, but it is not clear whether the incidence is greater than that observed in normal children during rapid periods of growth. Other possible rare and still unproven complications include acute pancreatitis, increased growth of pigmented nevi, and prepubertal gynecomastia.

Although early reports suggested a link between GH treatment and leukemia, Blethen and colleagues[177] reported that an analysis of 47,000 patient-years of treatment in greater than 19,000 children indicated that, in children without known risk factors, rhGH therapy was *not* associated with an increased occurrence of tumors or recurrence rate of leukemia or CNS tumors. Subsequent reports with an increasing number of patient-years confirmed that rhGH treatment does not increase the risk of primary malignancy in children and adolescents without preceding risk factors.[153] In a further study, Bell et al.[178] reported on 54,996 patients enrolled in the National Cooperative Growth Study database, of whom 42% had idiopathic GHD (n = 23,393), and 15% organic GHD (n = 8351). Among the children with organic GHD, the authors observed recurrence of intracranial tumors (1.8%), second neoplasms (0.5%), and new-onset malignancies without identifiable risk factors (0.1%), and suggested that rhGH may increase the risk of second malignancy in previously treated patients.[178] However, in the entire cohort the overall risk of malignancy was comparable to the reference population, with a standardized risk ratio of 1.12 (95% confidence interval [CI]: 0.75–1.61). In reports from the Childhood Cancer Survivor Study, the adjusted relative risk for second neoplasm in patients treated with rhGH compared with nontreated patients ranged from 3.21 to 2.15 (95% CI: 1.88–5.46 and 1.33–3.47, respectively).[179]

Another metaanalysis of published studies to estimate the potential relation between GH replacement treatment (GHRT) and recurrence/progression of intracranial tumors, searched three databases (PUBMED, EMBASE, Cochrane Library) to the end of July 2014. They collected more than 2232 cases and 3606 controls. The results indicated that recurrence/progression of intracranial tumors was not associated with GHRT (risk ratio [RR] 0.48, 95% CI: 0.39–0.56; for children RR 0.44, 95% CI: 0.34–0.54). In subgroup analysis, risks of recurrence/progression were decreased for craniopharyngioma, medulloblastoma, astrocytoma, and glioma, but not for functioning pituitary adenomas, nonfunctioning pituitary adenomas, and ependymomas. However, fluctuations in serum concentrations of GH and IGF1 were observed in neoplastic disease, which may affect tumor progression. In conclusion, GHRT seemed safe with respect to the risk of tumor progression.[180]

It is nevertheless the accepted practice to delay rhGH treatment in children with treated brain tumors until they have been shown to be tumor-free for at least 1 to 2 years.

Long-term follow-up has revealed a higher-than-expected incidence and mortality of colon cancer and Hodgkin disease. However, these data need to be put in context, as affected patients had been treated with high doses of human pituitary-derived GH given two to three times a week. Hence, one could speculate that the IGF1 concentrations generated by this mode of GH therapy may have been excessive. IGF1 concentrations at the upper end of the normal range (top quartile for colon and prostate and top tertile for breast) have been associated with colon, breast, and prostatic cancer.[181] Given that lower doses of GH are given on a daily basis, it would be incorrect—at this stage at least—to extrapolate the data from the earlier studies to the present treatment regimens.

The study on the *Safety and Appropriateness of Growth hormone treatments in Europe* (SAGhE)[182],[183],[184] was set up to address the issue of the long-term safety of rhGH treatment, including 30,000 low-risk children treated with rhGH between 1980 and 1990 in eight European countries who had attained 18 years of age by the census date. Patients were classified as having a low mortality risk if they were diagnosed with isolated idiopathic GHD, SGA, or ISS without genetic syndromes or defects. An early report of the results on the analysis of mortality for the cohort treated in France[182] showed an increase in the overall standardized mortality ratio (SMR), calculated at 1.33 (95% CI: 1.08–1.64), with the majority of deaths observed in the group with idiopathic GHD. The increase in all-cause mortality was associated with a higher rhGH dose of greater than 50 μg/kg/day (SMR 2.94; 95% CI: 1.22–7.07) but not with the severity of GHD or the duration of total GH exposure. When looking at the cause of death, there was no increase in the overall risk of cancer-related deaths, although numbers were relatively small. However, there was an almost 5-fold increase in deaths due to bone tumors (SMR 5.0; 95% CI: 1.01–14.63), as well as an increase in mortality from cardiovascular disease (SMR 3.07; 95% CI: 1.40–5.83) and cerebrovascular hemorrhagic events (SMR 6.6; 95% CI: 1.79–17.05).[182]

There was no clear carcinogenic effect of rhGH in patients with growth failure without other major disease. However, bone and bladder cancer incidence were significantly higher in GH-treated patients without previous cancer. Cancer risk was unrelated to duration or cumulative dose of rhGH treatment, but for patients treated after previous cancer, cancer mortality risk increased significantly with increasing daily rhGH dose (*P* trend < 0.001). The incidence of Hodgkin lymphoma increased significantly with longer follow-up (*P* trend $= 0.001$ for patients overall and 0.002 for patients without previous cancer).[184]

These results were in contrast with those published concurrently in a joint report from Belgium, the Netherlands, and Sweden.[183] The increase in mortality rate was not confirmed, the deaths observed were mostly due to accidents, and none were attributable to cardiovascular disease, cancer, or high dose of rhGH in the range of 0.048 to 0.054 mg/kg/day.[183]

A recent report from the SAGhE study showed no significant increase in overall mortality in low-risk patients (IGHD, ISS).[185] Conversely, in patients with increased risk (multiple pituitary hormone deficiencies [MPHD], comorbidities), there was an increased cardiovascular and hematological mortality rate associated with the underlying conditions.[185] Mortality was not associated with mean daily or cumulative rhGH dose.[185] Similar findings have been reported in other studies.[186] The latter study examined mortality in 3847 patients with IGHD, ISS, or SGA treated with GH between 1985 and 2010. They developed a mortality model of the Swedish general population born from 1973 to 2010, adjusting for birth characteristics, sex, age intervals, congenital anomalies, and calendar year to estimate the SMR and to apply this model to assess expected deaths in Swedish rhGH-treated patients. The mortality ratio was 1.43 (95% CI: 0.89–2.19, $P = 0.14$), with an observed/expected death ratio of 21/14.68. Using the advanced mortality model, the SMR was 0.955 (95% CI: 0.591–1.456, $P = 0.95$). Hence, there was no difference in mortality once was the correction for birth characteristics and congenital abnormalities were applied.

A further study of the GENESIS cohort[187] examined mortality in 9504 GH-treated patients followed for more than 4 years (67,163 person-years of follow-up). Forty-two deaths were reported (SMR, 0.77; 95% CI: 0.56–1.05). The SMR was significantly elevated in patients with a history of malignant neoplasia (6.97; 95% CI: 3.81–11.69) and borderline elevated for those with other serious non-GHD conditions (2.47; 95% CI: 0.99–5.09). No significant increases in mortality were, however, observed for GH-treated children with idiopathic GHD, ISS, SGA, Turner syndrome, SHOX deficiency, or a history of benign neoplasia.

A position statement from European Society for Paediatric Endocrinology, Growth Hormone Research Society, and Pediatric Endocrine Society[188] suggested that many of the disorders treated with GH in children and adults have an inherently higher mortality risk related to the underlying disorder; in most studies, therefore, the potential impact of GH treatment on overall mortality is difficult to distinguish from the impact of the underlying disorder.

Available data in children do not indicate an increased risk of new primary cancers in GH recipients, but the numbers of subjects followed up in the long term are still relatively small, and the data are incomplete. The likelihood of developing glucose intolerance or overt T2D during GH treatment in pediatric patients with GH deficiency or ISS is generally very low. Although the lifetime risk of glucose intolerance and T2D in a number of conditions treated with GH, including Turner syndrome and short SGA children, is higher than in the background population, GH treatment does not increase the incidence of T2D in these conditions in the short term. The position statement recommends careful monitoring of IGF1, adrenal and thyroid function, glycated hemoglobin, and potential scoliosis in those on GH treatment.

Endpoints of Therapy. Given the discussion outlined above in terms of efficacy, safety, and clinical governance, Table 18.11 illustrates some suggested outcomes that can be monitored and used as a basis of short- and long-term audit, as well as safety monitoring.

Growth Hormone–Releasing Hormone and Growth Hormone Secretagogues

In children whose GHD is due to a hypothalamic abnormality, treatment with GHRH would appear to be an appropriate therapeutic option. Both GHRH$_{1\text{-}44}$ and GHRH$_{1\text{-}29}$ are biologically active in humans. Unfortunately, although GHRH can be absorbed nasally, this route of administration has not proved to be effective, and treatment must be via subcutaneous or intramuscular injection, as is the case with rhGH. Direct comparisons of rhGH and GHRH have not been performed, but a number of studies indicate that GHRH administered once or twice daily can increase the growth rates of children with GHD. No specific therapeutic advantage of GHRH over rhGH has been demonstrated to date, although further studies are warranted to investigate optimization of dosage and frequency of administration.[189]

Since the discovery of GHRPs, a variety of small GHRPs and nonpeptidyl small-molecule GH secretagogues have been manufactured. These molecules are potent stimulators of GH release, especially when administered together with GHRH, and may be active when administered by intravenous, intramuscular, subcutaneous, nasal, and oral routes. These potential advantages must be balanced by the likelihood that normal GHRH production is required to see maximal benefit from such agents. Clinical trials of their therapeutic use have proven disappointing.[189]

KEY POINTS

- Growth hormone deficiency is treated with GH doses in the order of 0.025-0.35 mg/kg/day. Monitoring of IGF1 concentrations may enable optimal titration of the dose. The response to GH treatment is highly variable and this is due to a number of factors, including adherence to treatment, and polymorphic variations in genes that dictate GH responsiveness. Optimal timing of GH treatment is critical in dictating final height outcomes. Whilst it is widely recognised that GH treatment is safe and effective in GHD, the SAGhE study has recently raised concerns, although these data were not confirmed in patients from other countries within the SAGhE cohort. The data nevertheless clearly underline the need for ongoing monitoring of patients on GH treatment.

Transition to Adult Care

During the transition period from childhood to adulthood, statural growth can be complete, but somatic development still progresses, and peak bone mass continues to change. Low or undetectable GH concentrations during the transitional and adult ages have been associated

TABLE 18.11 Short-, Medium-, and Long-Term Endpoints of Growth Hormone Therapy in Children with Growth Hormone Deficiency

	ENDPOINT	RATIONALE	MEASURE
Short-Term	1. Growth acceleration	1. Assess response	1. Minimum response of greater than 2 cm/yr
	2. Reduction in adipose mass	2. Assess response	2. Skinfold thickness
	3. Correct dose	3. Optimize therapy	3. IGF1 and growth
	4. Vision and headaches	4. Raised intracranial pressure	4. Fundoscopy
	5. Assessment of limp	5. Slipped femoral epiphysis	5. X-ray
Medium-Term	1. Bone maturation	1. Rate of skeletal maturation	1. Yearly bone age
	2. Pubertal status	2. Early puberty or rapid progression	2. Six-monthly Tanner staging
	3. Correct dose	3. Optimize therapy	3. IGF1 and growth response; return to target height within 6 years of therapy
	4. Thyroid status	4. Altered status or evolving endocrinopathy	4. Yearly thyroid function tests
	5. Other hormones	5. Evolving endocrinopathy	5. Gonadotroph and corticotroph function
	6. Metabolic status	6. Insulin insensitivity	6. Fasting glucose and insulin
Long-Term	1. Growth	1. Outcome	1. Final height within target height of parents
	2. Bone mineralization	2. GH effect on bone	2. DEXA scan
	3. Malignancy risk	3. ? GH cancer link	3. Cancer registry
	4. Cardiovascular risk	4. Insulin resistance or GH effect (? long-term GHD)	4. Fasting glucose and insulin, blood pressure, fasting lipids

DEXA, Dual-energy x-ray absorptiometry; *GHD*, growth hormone; *GHD*, growth hormone deficiency; *IGF*, insulin-like growth factor.

with alterations in the somatic composition, an increased fat-free mass with increased blood lipid concentrations, a compromised peak of bone mass, and a reduction in muscular strength.[190,191]

Furthermore, a negative effect of GH discontinuation during the transition period on quality of life, psychological well-being, and depression has been reported.[192]

Therefore, resuming rhGH replacement therapy in patients with confirmed persistent GHD during the transition period after achievement of final height is recommended, as most studies have reported long-term improvement in body composition, bone health, quality of life, and lipid metabolism in adulthood.[193]

While there is undoubtedly evidence in favor of GH continuation from a metabolic point of view, there is nevertheless the problem of establishing whether the state of GHD, diagnosed in childhood, still persists in adolescence and adulthood. Previous studies have shown that the vast majority of patients diagnosed with idiopathic GHD in childhood, who have no structural pituitary abnormality on MRI, demonstrated normalization of GH secretion when retested in late adolescence or adulthood (66%–85% depending on the series, the test, and cutoff used).[194] It is therefore recommended that patients with childhood-onset GHD be retested after a washout period of at least 1 month[259-261] to confirm the diagnosis of GHD when statural growth is completed (growth velocity <1.5–2 cm/year).[195]

Current guidelines suggest that the diagnosis of adult GHD can be made without the need for performing GH stimulation testing in certain patient cohorts, such as those patients with organic HP disease (e.g., suprasellar mass with previous surgery and cranial irradiation) and biochemical evidence of MPHD (greater than or equal to three pituitary hormone deficiencies [PHDs]), together with low serum IGF1 concentrations (<–2.0 SDS), genetic defects affecting the HP axis (mutation in a transcription factor, e.g., *POU1F1*, *PROP1*, *HESX1*, *LHX3*, or *LHX4* or mutation in *GH1* or *GHRHR*), and HP structural brain defects.[196] In patients with less than or equal to two PHDs, low serum IGF1 concentrations (<–2.0 SDS) alone are not sufficient to make a diagnosis of adult GHD, and clinicians should perform one GH stimulation test to confirm the diagnosis.

In transition, patients with isolated GHD and the presence of organic HP disease (e.g., craniopharyngioma, pituitary hypoplasia, ectopic posterior pituitary, or previous cranial irradiation), the number of GH stimulation tests to be undertaken should be guided by the degree of clinical suspicion for GHD. If clinical suspicion is high, one GH stimulation test is sufficient, but if clinical suspicion is low, then a second GH stimulation test should be performed.

Transition patients with idiopathic isolated GHD and those with low-normal (between 0 and –2 SDS) or low (<–2 SDS) serum IGF1 concentrations should be retested for GHD with GH stimulation tests after at least 1 month following discontinuation of rhGH therapy. The vast majority of patients diagnosed with GHD in childhood who have no structural pituitary abnormality on MRI will have adequate GH secretion when retested in late adolescence or adulthood (66%–85% depending on the series, the test, and cutoff used).

It should be noted that the thresholds for GH insufficiency differ between the various dynamic tests, and such cutoffs need to be critically appraised. For transition patients, a feasible and validated GH stimulation test has been less well studied. Nevertheless, the insulin tolerance test (ITT), glucagon, macimorelin, and arginine used alone or with GHRH have been used to confirm/reconfirm GHD in adolescence.[197,198]

In this patient population, the ITT (using a GH cutoff point of ≤5.0 mg/L) may be utilized, as it has a higher specificity (100%) and sensitivity (96%) in detecting permanent GHD.[197] If the test is contraindicated (seizure disorder, cardio-/cerebrovascular disease) or unfeasible to perform, the glucagon stimulation test (using a GH cutoff point of 3 μg/L for normal-weight [BMI <25 kg/m^2] patients and overweight [BMI 25–30 kg/m^2] patients with a high pretest probability and a lower GH cutoff point of 1 μg/L for overweight [BMI 25–30 kg/m^2] patients with a low pretest probability and obese [BMI >30 kg/m^2] patients) and the macimorelin test (using a GH cutoff point ≤2.8 mg/L) can be considered as alternative tests. Arginine and levodopa testing have not been systematically evaluated and validated. Although these tests have low sensitivity and specificity in adults and transition patients with suspected GHD, they are still used by some centers.[199]

For between 25% to 75% of patients, the GH response to provocation is in the normal range, as would be expected from the previous discussion on testing, and probability theory needs to be employed to determine whether therapy should be continued or not. In the remainder, continuation of GH therapy should be considered, and these patients should be followed up by an adult endocrinologist. In these individuals, adverse changes in body composition, quality of life, and bone mineral density may be an indication to recommence GH treatment, although it is less likely that these individuals will develop adult GHD syndrome. In those patients with MPHD, GHD due to a congenital lesion, and GHD secondary to radiotherapy, surgery, or a mass lesion, the GHD is highly unlikely to reverse.

Indeed, GHD in adults results in decreased quality of life, increased risk of bone fracture, increased low-density lipoprotein (LDL)-cholesterol, and decreased HDL-cholesterol concentrations.[200] While some question the efficacy of protecting against osteoporosis, most believe that replacement therapy protects against its development.

Throughout transition, rhGH treatment will allow patients to reach full skeletal maturation, an appropriate somatic development, and an increase in lean mass. Stopping treatment, while not recommended, should be at least accompanied by monitoring GH-dependent endpoints. Similarly, GH is needed for maintaining healthy body composition, as it has been shown that cessation of rhGH treatment leads to an increase in visceral body fat.[200] Multiple reports have suggested that untreated GHD may cause cognitive dysfunction, fatigue, reduced sense of well-being, and altered mood. Standard lipid profiles improve with rhGH, with an overall lowering of total cholesterol, decreased concentrations of LDL-cholesterol, and unchanged triglyceride concentrations.[199,201] While no major cardiac function abnormality has been observed after GH discontinuation, an improvement in markers of endothelial dysfunction and positive effects on left ventricular mass, intraventricular septum, diastolic function, and stroke volume index have been reported with rhGH therapy.[199,202,203] Long-term controlled trials evaluating the effects of GH replacement on cardiovascular mortality and morbidity are still lacking, yet no positive trend in cardiovascular risk has been determined to date.[204]

Treating patients during transition is via rhGH given subcutaneously daily, similar to the pediatric population. However, as GH secretion varies during a lifetime, the dosing should follow the pattern determined by age and gender, along with any comorbidities and estrogen status. Physicians should consider starting rhGH at low doses and gradually titrating upwards, with an aim to provide an optimal response with the least expected side effects without a specific weight-based regimen. For patients younger than 30 years, most guidelines recommend initiating a dose of 400 to 500 μg/day, with a mildly higher dose during transition, with an increase in daily dosing by 100 to 200 μg/day every 1 to 2 months based on the individual's response.[199] Serum IGF1 concentrations should be monitored every 4 to 6 weeks until achieving the optimal maintenance dose. A repeat follow-up should be measured every 6 to 12 months. There is no consensus on the optimal IGF1 concentration, but in general the goal is maintaining a normal concentration within age- and sex-specific ranges.

KEY POINTS

- GH secretion should be retested at the end of linear growth in those with isolated GHD and a structurally normal pituitary gland on MRI. However, it is not necessary in those with organic HP disease, and those with 3 or more hormone deficiencies or proven genetic defects in the HP axis. Continuation of rhGH in those with persistent GHD is indicated in order to improve body composition, bone health, lean body mass, lipid metabolism, and quality of life.

CONCLUSIONS

To conclude, the diagnosis of GHD can be far from straightforward, and involves a careful clinical and auxological evaluation, together with the use of biochemistry, neuroimaging, and possibly genetic testing, although the latter is often not widely available.

Significant advances have been made in the past decades in refining the diagnosis and determining the causes of childhood GHD while optimizing its treatment. Neuroimaging has become an integral component of the diagnosis and leads to identification of structural pituitary and brain abnormalities. This, in turn, can define patients who need to be screened for additional pituitary deficiencies, as well as those who may have permanent GHD and who require GH replacement therapy in adult life. Neuroimaging can also enable the targeting of appropriate molecular analysis, and this in turn may enable genetic counseling. The development of novel technologies such as next-generation and possibly whole-exome and -genome sequencing, is likely to identify further causes of GHD and hypopituitarism in the fullness of time. Various questions nevertheless remain to be answered, including the variable penetrance of genetic mutations, the considerable phenotypic variability, the role of environmental factors, and the interaction between candidate genes suggesting a significant role of digenicity/oligogenicity. The recent development of therapeutic long-acting GH preparations may offer another mode of therapy, and this may be more acceptable to those with other underlying conditions, as well as to adolescents and young adults. It will help in those families that struggle with adherence with daily injections. Nevertheless, a number of challenges remain, not least the poor reproducibility of GH stimulation tests and the complex underlying molecular basis in some cases.

INTRODUCTION

Both energy intake and expenditure are regulated by a complex set of physiological signals that impact energy balance, and thus body weight. Understanding the processes underpinning energy intake and expenditure regulation is crucial to understanding human behavior and potentially holds the key to finding effective treatment options for both underweight and obesity. This chapter will discuss the sophisticated orchestration of eating behavior and energy expenditure (EE) and how these determine body weight.

COMPONENTS OF EATING BEHAVIOR

Eating is essential to survival, and it is therefore not surprising that evolutionary adaptations have rendered it enjoyable. Historically, throughout most of the evolution of human metabolism, food availability has been sparse, resulting in powerful biological mechanisms that drive eating. Ensuring adequate energy intake to sustain basic physiological processes such as resting metabolic rate (RMR) and physical activity is the most fundamental homeostatic function for survival. The physiological processes regulating energy availability are therefore incredibly complex and encompass peripheral signals that reflect nutrient intake and energy stores, the autonomic nervous system, and brain regions that control energy homeostasis. In addition to these homeostatic mechanisms, eating behavior is also governed by reward-related pathways, as well as psychological and cognitive decision-making processes.

Appetite Regulation

The Gastrointestinal Tract and Gut Hormones. The gastrointestinal (GI) tract is the first point of contact with ingested food and acts as the key interface between nutrients and brain centers that regulate energy homeostasis. Gut-derived signals convey information about the composition and energy content of ingested food to the brain. In this section, we review endocrine and neuronal signals originating from the GI tract and their role in controlling appetite and eating behavior (Fig. 19.1).

The GI tract is one of the largest endocrine organs in the body and contains populations of enteroendocrine cells (EECs) along its entire length.[1] EECs detect the presence of ingested nutrients and in response synthesize and secrete a multitude of metabolically active peptides.[1] Gut hormones, through their autocrine, paracrine, and endocrine actions, regulate digestive function, eating behavior, EE, and glucose homeostasis.[2] Table 19.1 summarizes key gut hormones and their effect on energy and glucose homeostasis.

In conditions of energy deficit, the orexigenic hormone and growth-hormone secretagogue, ghrelin, is secreted from P/D1 cells located predominantly in the gastric fundus.[3] Ghrelin stimulates appetite and drives the desire to eat. Circulating ghrelin levels peak prior to nutrient ingestion and decrease rapidly postmeal. Ghrelin exerts its orexigenic effects by acting on the hypothalamus, an effect that is exaggerated by prolonged fasting.[3]

In contrast, following ingestion of a meal, EECs along the GI tract sense nutrients and secrete a number of gut hormones, which inform central appetite-controlling circuits and peripheral tissues about nutrient availability. The anorectic hormones peptide YY 36 (PYY), glucagon-like peptide 1 (GLP-1), and oxyntomodulin (OXM) are all secreted from enteroendocrine L-cells in the GI tract and suppress appetite.[2]

GLP-1 receptors are widely expressed on multiple organs and tissues. The hypothalamic GLP-1 receptor (GLP-1R), however, has a key role in the regulation of eating behavior. In mice, stimulation of this receptor leads to reduced food consumption, whereas inhibition causes increased food intake.[4] Furthermore, GLP-1R

Figure 19.1 **Several Metabolically Active Peptides are Secreted Along the Gastrointestinal (GI) Tract that Regulate Energy and Glucose Homeostasis and Body Weight.** Gut hormones are secreted by discrete populations of enteroendocrine cells located along the GI tract, from the stomach to the colon. These include the orexigenic hormone ghrelin, anorectic peptides (glucagon-like peptide-1, peptide YY, cholecystokinin, oxyntomodulin) and pancreatic hormones (insulin, pancreatic polypeptide, amylin).

TABLE 19.1 The Role of Gut Hormones in Appetite Regulation and Energy Expenditure

Gut Hormone	Source and Stimuli	Sites of Action	Mechanism of Action	Function in Appetite and Body Weight Regulation
Ghrelin[3,144]	P/D1-type cells in: • Gastric antrum • Gastric fundus • Duodenum In response to: • Fasting • Regular mealtimes • Food cues	Following acylation by ghrelin O-acyl-transferase into acyl-ghrelin: • Growth hormone secretagogue receptor type 1a (GHSR1a) • Hypothalamus • Ventral tegmental area and other CNS reward areas • Vagus nerve	• Hypothalamus: MC4R inhibition • GHSR1a activation: stimulates AgRP and NPY neurons, increasing the drive to eat • Stimulates endocannabinoid release	• Increases appetite and motivation to eat • Increases the reward value of food • Increases gastric emptying and gastric acid production • Decreases insulin secretion
Glucagon-like-peptide 1 (GLP-1)[5,144,170]	• Enteroendocrine L-cells • Brainstem neurons In response to: • Exposure to nutrients, mainly glucose and fatty acids • L-cell stimulation by bile acids	GLP-1 receptor (GLP-1R) is widely present on central and peripheral tissues, including • Hypothalamus • Liver • Pancreatic beta calls • Skeletal and cardiac muscle • Vagus nerve	• Pancreatic β cells: stimulates insulin secretion • Hypothalamus: stimulation of afferent fibers in the paraventricular nucleus, suppressing the drive to eat	• Reduces appetite and suppresses motivation to eat • Reduces the reward value of food • Delays gastric emptying
Peptide YY 3-36 (PYY)[6,7,144]	• Enteroendocrine L-cells • Brainstem neurons In response to: • Exposure to nutrients, mainly protein and fatty acids	Y2 receptors: • Throughout the CNS • Vagus nerve	• Hypothalamic Y2 receptors: inactivation of NPY/AGRP neurons, suppressing the drive to eat	• Reduces appetite and suppresses motivation to eat • Reduces the reward value of food
Oxyntomodulin (OXM)[171]	• Enteroendocrine L-cells • Cosecretion with GLP-1	• GLP-1R • Glucagon receptors • Hypothalamus	• GLP-1R coactivation	• Reduces appetite and inhibits energy intake • Delays gastric emptying • Drives glucose-dependent insulin secretion
Cholecystokinin (CCK)[11]	• Enteroendocrine L-cells and I-cells • CNS In response to: • Exposure to nutrients, mainly protein and fatty acids	• CCK-1 receptor: stomach, pancreas, gallbladder • CCK-2 receptor: CNS	• Stimulates vagal afferents terminating in the NTS • Activates paraventricular nucleus of the hypothalamus	• Reduces appetite and inhibits energy intake • Delays gastric emptying • Inhibits gastric acid secretion • Stimulates insulin secretion

Continued

TABLE 19.1 The Role of Gut Hormones in Appetite Regulation and Energy Expenditure—cont'd.

Gut Hormone	Source and Stimuli	Sites of Action	Mechanism of Action	Function in Appetite and Body Weight Regulation
Gastric inhibitory polypeptide (GIP)[172]	- Enteroendocrine K-cells In response to: - Exposure to nutrients, mainly glucose and fatty acids	GIP receptor: - Pancreatic islet cells - Hypothalamus - adipose tissue	- β cells: glucose-dependent insulin release - CNS: induces proliferation of hippocampal progenitor cells	- Stimulates insulin secretion - Reduces energy intake
Gastric leptin[24,173]	- Gastric chief cells - Gastric endocrine P cells In response to: - Nutrient ingestion - Insulin secretion - CCK secretion	Leptin receptors: - Vagus nerve	Vagal afferents: - Fasted state: inhibits vagal afferents, increases energy intake - Fed state: stimulates vagal afferents, inducing satiety	- Regulates energy intake in a nutritional status–dependent manner
Amylin[174,175]	- Pancreatic β cells - Cosecreted with insulin In response to: - Glucose and fatty acid ingestion	Amylin-specific receptors: - CNS - Gastric fundus - Bone	- CNS (area postrema): receptor activation is transmitted to the NTS, inhibiting eating	- Suppresses postprandial glucagon secretion - Suppresses appetite and inhibits energy intake - Slows gastric emptying
Uroguanylin[176]	- Enterochromaffin cells in duodenum and small intestine In response to: - Nutrient ingestion	Guanylyl cyclase 2C (GUCY2C) receptors: - Intestinal epithelium - Hypothalamus	- At intestinal level regulates fluid and electrolyte balance	- Hypothalamus: promotes satiety and reduces energy intake
Neurotensin (NT)[177]	- Enteroendocrine cells - CNS In response to: - Nutrient ingestion, mainly lipids	Neurotensin receptors NTR1, NTR2, NTR3: - CNS, particularly hypothalamus - Pancreas - GI tract	- Increases POMC expression - Activates dopaminergic system in the midbrain	- Suppresses appetite - Reduces GI motility and gastric secretions - Promotes glucose-dependent insulin secretion - Facilitates fat translocation

knockdown in rodents results in hyperphagia and obesity,[4] highlighting the importance of this pathway in postmeal appetite suppression and weight regulation. GLP-1 also has a marked incretin effect, enhancing glucose-dependent insulin release and inhibiting glucagon secretion.[5] PYY has an important role in the postprandial suppression of eating. Peripheral administration of PYY to healthy human volunteers reduces appetite and energy intake.[6] However, when discussing the role of anorectic gut hormones in the regulation of energy balance and eating behavior, it is important to note that, in normal physiological conditions, their actions are synergistic, as highlighted by studies using administration of native peptides. For instance, GLP-1 and PYY administered in combination have a more potent effect on appetite suppression compared with either of the two hormones alone.[7,8] Furthermore, GLP-1, PYY, and OXM have an additive effect on promoting satiety and reducing energy intake, whereas gastric inhibitory polypeptide (GIP) and cholecystokinin (CCK) enhance the effects of GLP-1.[7,9-11]

Gut hormone secretion from EECs is regulated by a combination of their nutrient exposure, as well as neural and endocrine pathways.[12] Interestingly, the melanocortin-4 receptor (MC4R) is present on EECs, additionally regulating ghrelin and PYY secretion.[13] Furthermore, gut hormones influence energy homeostasis through interactions with the microbiome and bile acids. For instance, bile acids in humans stimulate EECs via TGR5 activation, which results in gut hormone secretion. Interestingly, administration of bile acids to humans leads to release of GLP-1 and improved glucose homeostasis.[14]

Pancreatic Hormones and Appetite Regulation. In addition to their role in glucose homeostasis, pancreatic hormones also contribute to appetite regulation. Insulin receptors are present in the arcuate nucleus of the hypothalamus (ARC), and their activation results in appetite suppression.[15] The pancreatic hormone amylin acts centrally as a satiety signal and reduces both food intake and body weight.[16] Both in animal and human studies, exogenous administration of amylin results in reduced energy intake and weight loss.[16] Amylin exerts its effects by acting upon receptors that are widely distributed across the central nervous system (CNS), including the hypothalamus. Amylin also directly acts on the area postrema of the hindbrain, offering an additional route for the regulation of energy homeostasis independent of hypothalamic circuits.

Taste, Visual, Gustatory, and Olfactory Cues and Appetite Regulation. The chemosensory properties of food are among the key determinants of food-related decision-making. Visual, gustatory, and olfactory cues can influence the motivation and decision to eat.[17] Taste and smell are key determinants of food choice and enjoyment, and gut hormones have a role in modulating the perceived palatability of the chemosensory properties of food. Ghrelin modulates olfactory responsiveness by increasing CNS responses to olfactory stimuli, and ghrelin levels directly correlate with olfactory activity.[18] The presence of gut hormones in saliva and their cognate receptors on taste buds implicates gut hormones in modulating gustatory function. Preclinical studies suggest that increasing PYY concentrations in saliva alters food preference, reduces energy intake, and reduces body weight.[19]

The oral cavity is the first point of contact with food, and chemoreception by taste receptors in the oral cavity is the first step in recognition of and metabolic responses to ingested nutrients.[20] *In vitro* and *in vivo* studies suggest that detection of nutrients by taste receptors modulates neuronal and endocrine signaling engendering downstream effects on energy homeostasis. Furthermore, a number of gut hormones, including PYY, ghrelin, insulin, and GLP-1, have been detected in saliva and are thought to have a role in modulating taste signaling and perception, particularly in response to sweet and fatty stimuli.[17,21] GLP-1 is expressed in sweet- and umami-sensing cells, and GLP-1 null mice have reduced taste sensitivity to sweet taste.[22,23] In addition, taste receptors are also present along the entire GI tract, including on EECs, and their activation has been linked to GLP-1 release in response to glucose ingestion.[23]

Leptin, Growth Differentiation Factor 15, and Endocannabinoids

Leptin. The adipokine leptin is secreted from adipose tissue and acts as a signal of long-term energy availability, signaling both the availability and stability of long-term energy stored in adipose tissue.[24] Leptin secretion promotes satiety by modulating orexigenic neurons in the ARC in an opposing manner to ghrelin.[24] Leptin deficiency in humans results in hyperphagia and severe obesity, which is reversed by leptin administration. A recent report of exogenous leptin treatment in a patient with leptin deficiency highlights key interactions between gut hormones. Supplementation resulted in significant rises in meal-stimulated insulin, GLP-1, and PYY levels and a reduction in ghrelin levels, highlighting the regulatory role of leptin.[25] Administration of leptin, however, in adults with obesity without leptin deficiency does not lead to significant weight loss.[26]

Growth Differentiation Factor 15. Growth differentiation factor 15 (GDF15), a metabolically active protein encoded by the macrophage inhibitory cytokine 1 gene, was originally described to be a stress- and inflammation-induced cytokine secreted in response to macrophage activation.[27] A growing body of evidence supports the role of GDF15 as an independent regulator of appetite and body weight. GDF15 knockout mice have increased adiposity and body weight associated with increased spontaneous food intake.[28] However, the phenotype can be reversed by infusion of recombinant GDF15 in concentrations equivalent to circulating levels in healthy humans, demonstrating that GDF15 has a role in energy homeostasis.[28] Circulating GDF15 acts on the ARC; however, it primarily mediates its anorectic effects via the area postrema and the nucleus of the solitary tract (NTS).[29]

Endocannabinoids. The chemosensory properties of fatty acids in the oral cavity during eating lead to secretion of lipid-derived endocannabinoid signals such as anadamide.[30] Endocannabinoids bind to cannabinoid receptors in the CNS and on peripheral tissues. Activation of the cannabinoid receptor 1 (CB1R) has orexigenic effects, whereas blockade in animal models reduces energy intake. Anadamide levels have been shown to increase with prolonged fasting, and circulating levels mirror plasma fatty acid levels.[30] Meal-stimulated changes in endocannabinoids have also been shown to depend on the palatability of ingested food and may relate to the perceived pleasantness of food, although the exact role of the endocannabinoid system in appetite regulation remains incompletely understood.

KEY POINTS

- The gastrointestinal (GI) tract plays a key role in energy regulation. Enteroendocrine cells across the entire length of the GI tract sense ingested nutrients and, through secretion of orexigenic (e.g., ghrelin) and anorectic (e.g., PYY, GLP-1, OXM) gut hormones, transmit signals of energy availability to the brain. Pancreatic hormones such as amylin (anorectic), the adipokine leptin, and meal-induced endocannabinoids also have a role in appetite regulation. However, these metabolic signals of appetite can be overridden through powerful hedonic responses to food cues.

The Vagus Nerve: The Role of Vagal Signaling in Appetite Regulation

The vagus nerve provides bidirectional communication between the brain and GI tract. Vagal afferent neurons act as early integrators of peripheral energy signals. Their firing is influenced by multiple signals and changes in the GI milieu, including gut hormones, leptin, gut-derived lipid signals, the intestinal microbiome, and GI inflammatory signals. Receptors for leptin, ghrelin, CCK, GLP-1, and PYY have been located on vagal afferents. Vagal afferents convey signals of energy availability to the NTS in the brainstem.[31] Furthermore, the vagus nerve receives direct synaptic signaling from EECs along the GI tract. EECs project synapse-like structures, called neuropods, that synapse directly with vagal neurons, allowing them to directly transmit signals relating to energy availability to neurons in one synapse to the brainstem.[32] Vagal efferent fibers emerge from the dorsal motor nucleus of the vagus nerve in the medulla that contain parasympathetic efferents and innervate the musculature and mucosal layer of GI organs.[33] Vagal efferent signals from the brain to the GI tract and together with metabolic and endocrine signals coregulate nutrient absorption and mobilization.[31] Vagal efferent signals also synapse onto enteric neurons, providing a link between the central and enteric nervous systems.[33]

Vagal afferents display inherent plasticity, responding to both short- and long-term changes in energy availability and altering their responsivity to gut-derived signals accordingly.[34] For instance, fasting increases CB1R expression and promotes orexigenic signaling, an effect that is quickly reversed following energy intake.[30] Up- and downregulation of gut hormone receptors is also a dynamic process. Both ghrelin and CCK have been implicated in regulating the phenotype of the vagus nerve, altering its sensitivity to gut-derived signals, possibly in an opposing manner.[31]

Hypothalamus and the Central Nervous System: Integration of Energy Availability Signals

Peripheral signals relating to energy and nutrient availability are conveyed to the CNS, where numerous neuronal circuits integrate these to control appetite and eating behavior.[35] NTS neurons project into the ARC. Within the CNS, the hypothalamus is the main center integrating peripheral homeostatic signals of energy availability into central networks.

Hypothalamic nuclei containing neurons expressing neuropeptide Y (NPY) and agouti-related protein (AgRP) become active in conditions of energy deficit and drive orexigenic responses; conversely, in conditions of energy surplus, proopiomelanocortin (POMC) neurons generate anorectic responses, in a mutually exclusive manner.[36] POMC neurons coexpress cocaine- and amphetamine related transcript (CART). Ghrelin activates NPY and AgRP neurons, generating a sensation of hunger and driving eating, an effect that is exacerbated by prolonged fasting.[3] In contrast, anorectic peptides including PYY, GLP-1, and OXM activate POMC neurons. In the paraventricular nucleus of the hypothalamus, the melanocortin melanocyte-stimulating hormone

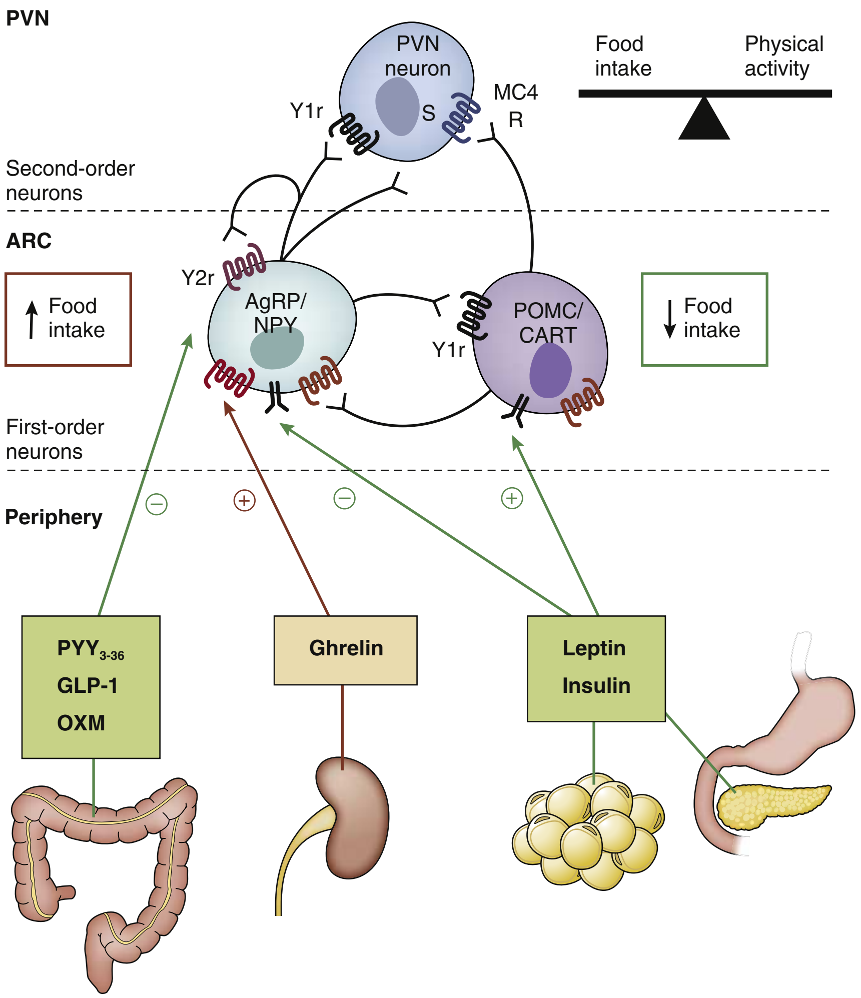

Figure 19.2 **Peripheral Signals of Energy Availability are Integrated in the Hypothalamus.** First-order neurons are located in the arcuate nucleus of the hypothalamus (ARC). Neurons expressing neuropeptide Y (NPY) and agouti-related protein (AgRP) become active in conditions of energy deficit and drive orexigenic responses. Ghrelin activates NPY and AgRP neurons.[36] In conditions of energy surplus proopiomelanocortin (POMC) neurons generate anorectic responses. POMC neurons coexpress cocaine- and amphetamine related transcript (CART). Anorectic peptides including PYY, GLP-1, and OXM activate POMC neurons and inhibit NPY/AgRP. Rises in insulin and leptin levels also have inhibitory effects on NPY/AgRP. In the paraventricular nucleus of the hypothalamus (PVN), melanocortin melanocyte-stimulating hormone a (a-MSH), subsequently activates the melanocortin-4 receptor (MC4R), which generates a feeling of satiety, improves insulin sensitivity, and increases energy expenditure.[37] Depending on energy needs versus availability, NPY/AgRP and POMC neurons are activated in a mutually exclusive manner.[36]

subsequently activates the MC4R, which generates a feeling of satiety, improves insulin sensitivity, and increases EE.[37] In conditions of energy deficit, the receptor is inhibited by AgRP (Fig. 19.2).[37] Loss-of-function MC4R mutations result in hyperphagia, severe obesity, rapid growth, and impaired glucose metabolism. MC4Rs have been localized on EECs and are thought to contribute to regulation of gut hormone secretion.[13] Ascending hypothalamic projections convey information on energy availability to higher CNS centers involved in the perception and control of eating, which are summarized in Table 19.2.

Research utilizing functional magnetic resonance imaging (fMRI) in combination with measurement or administration of gut hormones or during performance of food-related tasks has led to an increased understanding of how these incredibly complex pathways ultimately determine eating behavior.[38] Through measuring the degree of blood oxygen level–dependent contrast, a signal of activity-related change, these studies have demonstrated that gut hormones directly modulate neural activity in these brain centers.[39] Following a period of fasting, activity in the hypothalamus has been shown to correlate with subsequent energy intake.[40] Circulating ghrelin levels in the fasted state correlate with neural activity in the amygdala, orbitofrontal cortex (OFC), anterior insula, and striatum,[41] and administration of ghrelin increases food-cue reactivity. When ghrelin is administered in the fed state, it increases neural activity and food cue reactivity to a degree comparable to the fasting.[41,42] Following a meal, PYY and GLP-1 synergistically modulate activity in the brain's appetitive network and reduce the reward value of food.[39] A negative correlation has been demonstrated between PYY levels and activity in the brain's reward centers.[39] A study comparing the effects of a meal compared with the effects of PYY and GLP-1 infusions, administered separately and together, demonstrated that PYY and GLP-1 caused changes in brain activity and reduced energy intake comparably to a meal.[7]

The Role of Genetics and Epigenetics

Both homeostatic and hedonic drivers for eating behavior are subject to individual predisposition from genetic and epigenetic factors.

Population-wide studies have demonstrated that up to 85% of variability in body mass index is heritable. For example, the obesity risk variant rs9939609 in the fat-mass and obesity-associated (*FTO*) gene is linked to increased appetite levels and preferences for energy-dense foods. Normal-weight adults homozygous for the rs9939609 variant have higher postprandial circulating ghrelin levels, increased hunger, and altered responses to food cues in CNS reward regions compared with subjects with the low-risk variant.[43] In addition to genetic factors, epigenetic factors from the environment passed from one generation to the next through perinatal programming may contribute more acutely toward an individual's body weight.[44] Although the degree to which body weight is influenced by genetics remains unknown, it is evident that large, multifactorial variability exists between individuals in their predisposition to gain weight, appetite levels and food preference, and how their biology responds to attempts conditions or energy excess or restriction.

KEY POINTS

- The vagus nerve provides bidirectional communication between the brain/central nervous system and gastrointestinal tract. Vagal afferent signals are responsive to short- and long-term alterations in energy availability, and their responsiveness is highly adaptable based on nutritional state. Hypothalamic nuclei containing neurons expressing neurons expressing neuropeptide Y and agouti-related protein are active in conditions of energy deficit and drive orexigenic responses; conversely, proopiomelanocortin neurons (which coexpress cocaine- and amphetamine related transcript) generate anorectic responses when energy requirements are met. Importantly, eating behavior and body weight are influenced by individual genetic predisposition, with up to 85% of body mass index variability ascribed to genetic differences.

TABLE 19.2 Central Nervous System Areas Involved in the Control of Appetite and Eating

Brain Area	Role in Eating Behavior
Hypothalamus	Homeostatic control
Hippocampus	Learning and memory Links energy balance to incentive behavior
Amygdala	Emotional learning, assigning of value Encodes palatability of foods Link between homeostatic and hedonic interactions
Insula	"Ingestive" and "gustatory" cortex Encodes sensory information of taste, integrated with sensory cues to form flavor Responds to food cues and gut hormones
Nucleus of the solitary tract	Afferent target for vagus nerve
Ventral tegmental area	Encodes nutritional and reward values of food Generates value and motivational signals
Cerebellum	Integrates and coordinates somatic-visceral responses to food
Striatum: **Caudate nucleus** **Putamen** **Nucleus accumbens**	Encodes motivational and incentive properties of food Anticipatory reward Connected to all other brain regions of eating behavior Links motivation to action
Orbitofrontal cortex	Reward encoding Integration of sensory, cognitive, and reward aspects
Cingulate cortex	Decision making
Prefrontal cortex	Translation of internal and external cues to behavior, food-related decision-making

COMPONENTS OF ENERGY EXPENDITURE

Total daily EE (TDEE) is comprised of three main components: RMR, thermic effect of food (TEF), and physical activity EE (Fig. 19.3).

Resting Metabolic Rate

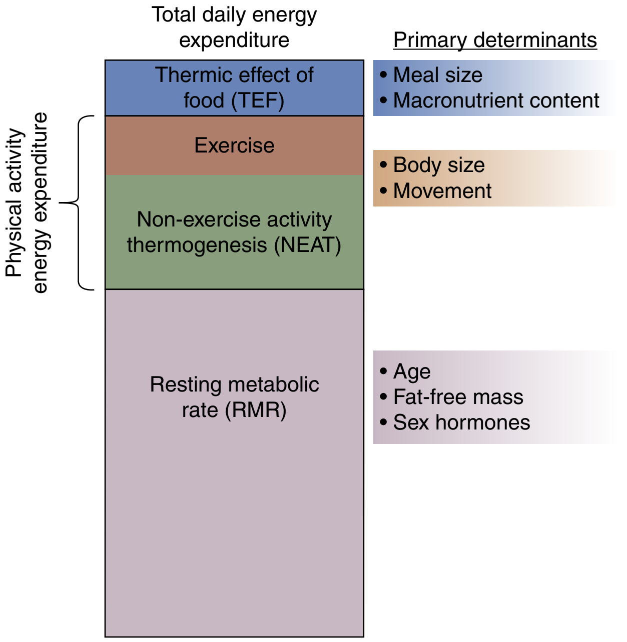
Basal metabolic rate (BMR) is the energy required to sustain basic physiological functions (e.g., cellular function, respiration, circulation, neurological function) by the body at complete rest and accounts for approximately 60% to 70% of TDEE in sedentary individuals. BMR is measured under strict, standard conditions that include being awake in the supine position after 10 to 12 hours of fasting and 8 hours of physical rest, with the measurement obtained under thermoneutral conditions.[45] Because these conditions are not always met, this is often referred to as RMR, which is approximately 5% higher than BMR. Although BMR and RMR are often used interchangeably, we will use the term RMR for consistency throughout the chapter, as that is what is more commonly measured in clinical settings.

RMR is measured in clinical and research settings using indirect calorimetry. These systems are open-circuit, meaning that subjects inspire ambient air, and the difference between inspired and expired concentrations of oxygen (O_2) and carbon dioxide (CO_2) is used to calculate EE[46] and substrate oxidation (e.g., fat and carbohydrate) (Fig. 19.4A). In clinical settings, subjects should be overnight fasted (at least 8 hours) and refrain from moderate-to-vigorous exercise for 24 to 48 hours. When these conditions are met, a coefficient of variation between repeated measurements is approximately 5%.[47]

Many research studies and some clinical settings measure EE with metabolic carts (Fig. 19.4B). Advances in technology have led to the development of "handheld" or "portable" indirect calorimeters (Fig. 19.4C). Many of these devices measure only O_2 consumption, and thus cannot measure substrate oxidation. Although these devices are accessible in clinical settings, they typically are less accurate compared with metabolic carts.[48,49]

Numerous predictive equations have been developed to estimate RMR. The most prevalent equations are the Harris–Benedict[50] and Mifflin–St. Jeor[51] formulas, which use sex, age, height, and weight to estimate RMR. Other equations include additional variables such as body composition and ethnicity; however, these equations often have been developed for use in specific populations. While most equations do well on a group level, individual-level accuracy is poor.[52] For example, the Harris–Benedict equation may under- or overpredict RMR by greater than 10% in approximately 30% to 40% of adults; similarly, the Mifflin–St. Jeor equation may under- or overpredict RMR in approximately 20% to 50% of adults.[53]

Determinants of Resting Metabolic Rate. RMR is primarily determined by body size and composition. Specifically, fat-free mass (FFM)—the sum of total body water, total body protein, carbohydrates, nonfat lipids, soft tissue minerals, and bone minerals—accounts for 50% to 70% of the variability in RMR between individuals. Although FFM is often considered to be synonymous with muscle mass, FFM is comprised of a number of energetically heterogeneous tissues. For example, the heart, liver, kidney, and brain constitute 5% to 6% of body weight but contribute to approximately 60% to RMR.[54,55] Skeletal muscle, adipose tissue, and bone constitute a much larger percentage of total body weight but contribute only approximately 20% to 30% to RMR (Table 19.3).[54,55] Although the metabolic rate of skeletal muscle per gram of tissue is lower than that of other organs, it is a strong predictor of RMR because of its larger mass.[54] Similarly, adipose tissue uses a small amount of energy per kilogram (4 kcal/kg/day) but may also substantially contribute to RMR in individuals with excess fat mass (FM).[56]



Total daily energy expenditure
Primary determinants
Thermic effect of food (TEF)

• Macronutrient content
Physical activity energy expenditure
Exercise
Non-exercise activity thermogenesis (NEAT)
• Body size
• Movement
Resting metabolic rate (RMR)
• Age
• Fat-free mass
• Sex hormones

Figure 19.3 Major Components and Determinants of Total Daily Energy Expenditure.

RMR decreases with advancing age, primarily due the age-associated decreases in FFM. However, organ- and tissue-specific metabolic rates are also lower in elderly individuals compared with young adults.[57] These differences are likely due to reductions in the cellular fraction of organs and tissues with age,[58] which are driven by reduced sodium-potassium adenosine triphosphatase activity, decreased norepinephrine from lower physical activity and dietary intake, and reduced protein synthesis.[59] Across the lifespan, absolute RMR is generally higher in males than females, but these differences are not apparent when accounting for inherent FFM differences between sexes.[60]

RMR fluctuates during the menstrual cycle, being approximately 6% to 7% higher in the luteal compared with the follicular phase,[61] which may relate to higher estrogen and progesterone in the luteal phase.[62] The impact of female sex steroids on RMR has been studied using pharmacological approaches to suppress gonadal function. In premenopausal women, suppressing gonadal function decreases RMR by 71 kcal/day compared with RMR measured in the follicular phase.[63] In a longer study that involved suppressing gonadal function for 5 months, RMR decreased 54 kcal/day, but in women in whom

TABLE 19.3 Contribution of Organs and Tissues to Resting Metabolic Rate (RMR)

Tissue	Tissue Weight (% Body Weight)	Tissue Metabolic Rate (%RMR)
Organs	<6	58
Skeletal muscle	40	22
Adipose tissue	21	<5
Miscellaneous (skin, bone, gut, etc.)	33	16

Values from a male without obesity. Organs and tissues make up <6% of body weight but contribute to >50% of RMR. Values from Dulloo AG, Jacquet J, Solinas G, et al. Body composition phenotypes in pathways to obesity and the metabolic syndrome. *Int J Obes*. 2010;34:S4–S17.

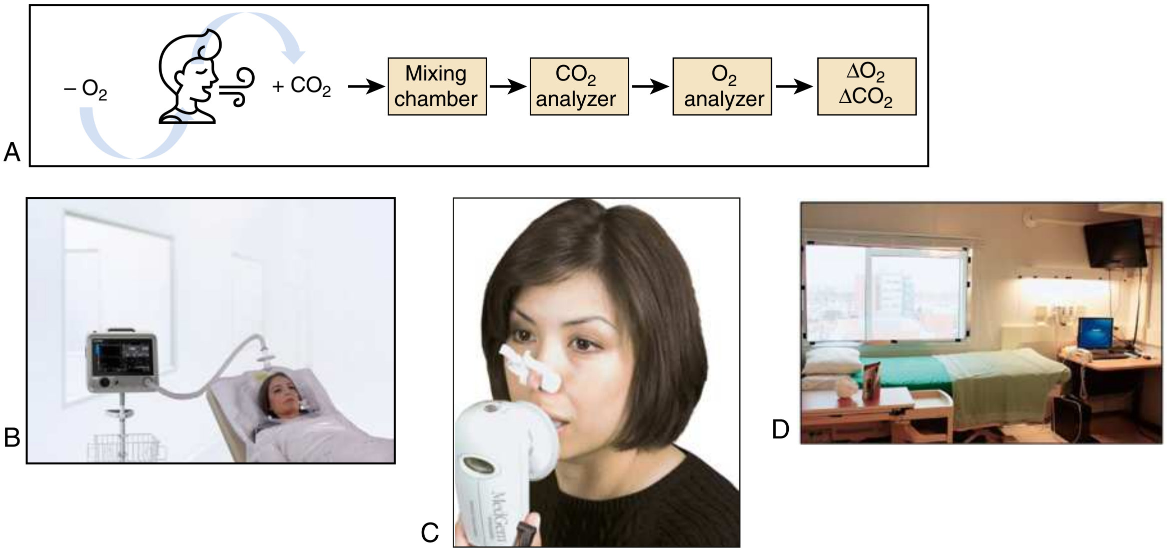

Figure 19.4 Basic Concepts and Examples of Indirect Calorimetry Systems. **A,** Simple schematic of metabolic system components. Expired oxygen (O_2) and carbon dioxide (CO_2) are transferred to a mixing chamber, where breath samples are homogenized. CO_2 and O_2 analyzers assess the concentrations of expired gases compared with gas concentrations in the room, which can then estimate O_2 consumption and CO_2 expiration. These values are then used in equations to estimate energy expenditure. **B,** Example of a metabolic cart with ventilated hood (Q-NRG, COSMED HQ, Italy – Test of Resting Energy Expenditure with Canopy hood © 2021, COSMED, Rome, Italy [www.cosmed.com]). **C,** Example of a handheld indirect calorimetry device (MedGem, Microlife, Clearwater, FL, USA). **D,** Example of whole-room indirect calorimetry, located at the University of Colorado, Anschutz Medical Campus.

estradiol was added back, this decrease in RMR was prevented.[64] The effect of oral contraceptives on RMR is unclear, with some studies showing higher RMR in pill-users versus non-pill-users, while others show no difference or even lower RMR among women on oral contraceptives.[62] In males, long-term changes in sex steroids may also contribute to decreasing RMR with age, but the evidence is conflicting. For example, 3 weeks of endogenous sex steroid suppression in older males (age range: 50–80 years) with add back of transdermal estradiol, testosterone, or both also did not affect RMR.[65] However, in another study testosterone and growth hormone replacement in hypopituitary males (age range: 33–77 years) increased RMR over 6 weeks.[66]

Thermic Effect of Food

TEF is the energy expended to digest, absorb, and store food. TEF accounts for approximately 10% of TDEE in adults in energy balance consuming a mixed diet.[67] TEF is proportional to the energy content of a meal and influenced by macronutrient content, with protein (20%–30% of the energy content of consumed food) and alcohol (10%–30%) eliciting a greater TEF response than fat (0%–3%) or carbohydrate (5%–10%).[67]

While it was initially thought that TEF does not decrease with age,[68] more recent investigations report that it is lower in older adults compared with younger individuals.[69,70] Although speculative, this age-associated decline in TEF may be attributed to differences in β-adrenergic sensitivity, which would reduce postprandial sympathoadrenal stimulation.[69] There is some controversy regarding TEF changes with weight loss or gain and in individuals with or without obesity, because some—but not all—investigations have reported differences in TEF.[71] Similarly, some studies have suggested that a low TEF predicts future weight gain,[72] which has not been corroborated by others,[73] as discussed later.

Physical Activity Energy Expenditure

PAEE is the most variable component of TDEE and is determined by body size and movement. PAEE is sometimes expressed as physical activity level (PAL), which is the ratio of TDEE to RMR. In free-living conditions, PAL is highly variable between individuals. For example, PAL of nonambulating chair-bound individuals is approximately 1.2, while PAL values of greater than 4 have been recorded in elite endurance athletes during competition, but are not sustainable (i.e., Tour de France cyclists, sled hauling across the Arctic, or Nordic skiers).[74] PAL values around 2.8 to 3.0 are sustainable for short periods of time among elite athletes during rigorous training, but likely do not represent year-round averages.[74] PAL within the general population lies between 1.4 and 1.69 in adults who are sedentary or perform light activity, 1.7 and 1.99 in adults with an active lifestyle, and 2.0 and 2.4 in adults with a vigorously active lifestyle.[45,74]

PAEE can be further categorized as exercise thermogenesis and nonexercise activity thermogenesis (NEAT), which encompasses EE associated with occupation, sitting, standing, and ambulatory activities. However, PAEE is challenging to measure. In research settings, PAEE can be measured using whole-room indirect calorimetry (Fig. 19.4D). These units resemble small hotel rooms and can assess distinct parts of EE such as exercise and sleep. However, because subjects are confined to a small space, often with restricted specific time schedules, this does not accurately measure free-living PAEE and TDEE. The doubly-labeled water (DLW) method is the most accurate way to measure free-living TDEE.[75,76] With this method, subjects ingest a dose of stable (nonradioactive) hydrogen (^2H, deuterium) and oxygen (^{18}O) isotopes. The labeled ^2H exits the body as water (primarily urine, with smaller amounts lost in breath and sweat), but the labeled ^{18}O exits the body through both water and expired CO_2. Thus, the difference in elimination rates of these two isotopes reflects CO_2 production over the period of measurement (typically 7–14 days), which is then used to estimate TDEE.[75,77] PAEE can then be calculated as TDEE – RMR, and PAL can be calculated as TDEE/RMR.

A limitation of the DLW approach is that it does not provide details about the nature or intensity of physical activity patterns. Thus, wearable activity monitors are better suited for this purpose. While most devices have reasonable accuracy in determining physical activity and sedentary behavior patterns, they *estimate* PAEE/TDEE using predictive equations, and there is substantial variability in the accuracy of both commercial and research devices.[78] Activity monitors that use additional biosignals (e.g., heart rate) to estimate PAEE and TDEE may improve accuracy.[78]

Brown Adipose Tissue and Uncoupled Respiration

Brown adipose tissue (BAT) is highly vascularized and richly innervated by the sympathetic nervous system (SNS) and generates heat through uncoupling of oxidation and phosphorylation by uncoupling protein 1 (UCP1) in a process known as "nonshivering thermogenesis" (NST).[79] Transient receptor potential (TRP) cation sensors on the skin sense the decrease in temperature and transmit signals to the hypothalamic preoptic area, evoking an increase in SNS activity, which stimulates both shivering and NST in several tissues, including BAT.[80] Until recently, BAT in humans was thought to be present in significant volume and activity only in infants.[81] However, evidence began to accumulate in the early 2000s that many humans have substantial BAT depots. In adult humans, BAT is most often observed in the cervical, clavicular, and paraspinal regions. Retrospective analysis of large cohorts of clinical positron emission tomography/computed tomography scans suggests that BAT is observable in approximately 5% to 10% of scans.[82] However, studies of cold-exposed individuals have shown metabolically active BAT is detectable in most adults.[83-86] The total volume of activated BAT is approximately 50 to 200 g in most humans studied, but has been reported to be as high as 1 kg.[87] Cold-induced BAT activity decreases with age[88-90] and is inversely associated with body fatness,[89,91,92] but whether a decline in BAT activity contributes to the development of human obesity is unclear.[93] However, during experimental cold exposure, skeletal muscle is the primary source of both shivering thermogenesis and NST.[84]

Although BAT contributes to EE and thermogenesis in rodents, the contribution of BAT to EE in humans is controversial.[79] Indirect evidence suggests a role for BAT in supporting RMR. Stimulated human BAT consumes approximately 150% more O_2 than white adipose tissue *in vivo*,[94,95] and the presence of active BAT is associated with higher RMR.[91,96] BAT may also contribute to TEF, because the postprandial increase in EE is higher in individuals with greater amounts of BAT,[97] and a variant in the *UCP1* gene is associated with lower postprandial EE.[98] Interestingly, it has recently been shown that meal consumption increases circulating levels of the BAT secreted hormone secretin. Chronic infusion of modified human secretin transiently elevates EE in diet-induced obese mice, and acute secretin infusion in humans increases BAT glucose uptake.[99]

Given the potential effect of BAT on EE in humans, there has been increased interest in understanding whether BAT activation can be used as a means to induce weight loss. Only a few studies have been performed in humans to determine the potential to increase BAT activity and EE and induce weight loss through cold exposure. Both acute and chronic interventions have reported increased BAT in response to intermittent cold exposure,[86,100-103] and others have reported concomitant small increases in RMR.[101,102,104] Theoretically, increased RMR may induce weight loss if sustained over time. However, most investigations of BAT-inducing interventions have reported no changes in body weight,[86,103] although one noted a small decrease in FM after 6 weeks of exposure to 62°F.[102] It should be noted that almost all of these studies were performed on lean adults; whether there would be an impact on body weight in people with overweight or obesity is not known. Additionally, few of these studies have measured the impact of cold exposure on energy intake. If energy intake increases in response to cold exposure, this could attenuate or even reverse the intended effects on body weight.

Because BAT is activated by SNS activity, it is possible that pharmacological or nutritional agents that stimulate SNS activity can increase BAT activity. One potential agent is mirabegron, a β3 agonist used for the treatment of hyperactive bladder. Acute treatment with 200 mg oral mirabegron increased BAT activity and RMR by approximately 200 kcal/day; however, this was accompanied by significant increases in resting heart rate and systolic blood pressure.[105] In a more recent study by the same group, 14 overweight women were treated with 100 mg mirabegron for 4 weeks. Chronic mirabegron therapy increased BAT metabolic activity and RMR, but there were no changes in body weight or composition.[106] However, recent evidence suggests that human BAT contains few β3 receptors, suggesting that the effects of mirabegron are due to off-target biding to β1 and β2 receptors.[107]

Due to the untoward effects of β-adrenergic receptor agonists, there is an interest in knowing whether food-derived stimulants activate BAT. The most heavily studied food-derived substances are capsaicin, a major component of red chili peppers that is responsible for its pungent taste, and capsinoids (capsaicin-like compound found in nonpungent red peppers). In rodents, oral administration of capsaicin activates the TRP vanilloid 1 channels located within sensory nerves of the GI tract, increasing SNS activity to BAT and whole-body O_2 consumption.[108,109] Chronic consumption of capsaicin or capsinoids upregulates BAT UCP1 protein and decreases body fat.[110] However, translating these studies to humans is difficult, because capsaicin in equivalent amounts provided to rodents would be greater than humans could tolerate. However, oral ingestion of capsinoids has been shown to increase whole-body EE in humans with high levels of BAT.[110] Cold-activated BAT is also increased by chronic consumption of capsinoids.[111] Another compound that has been studied in humans is catechin, a class of polyphenols found in green tea. Studies in rodents have demonstrated that supplementation with catechins increases UCP1 in both brown and white adipocytes.[112] Similar to studies with capsinoids, oral ingestion of tea containing catechins increases EE, but only in those with high levels of cold-stimulated BAT.[113] Although these studies are intriguing, there is limited evidence that dietary compounds activate BAT in humans and even less evidence that there is a stimulatory effect on EE or an effect on body weight.

KEY POINTS

- Total daily energy expenditure is comprised of three main components: 1) resting metabolic rate, which is the largest part of total daily energy expenditure (TDEE) and is primarily determined by body size and composition, 2) thermic effect of food, which comprises approximately 10% of TDEE and is mainly determined by energy and macronutrient intake, and 3) physical activity energy expenditure, which is the most variable component of TDEE, is determined by body size and movement, and can be subdivided into exercise and nonexercise activity thermogenesis. Recent evidence suggest that brown adipose tissue is present in a large proportion of adults, but its contribution to the development of obesity is unclear.

BODY WEIGHT REGULATION

Body Weight Regulation and Eating Behavior: Beyond Homeostasis

Eating is a behavior that is critical for survival. However, environmental changes in the past few decades have resulted in food surplus. Coupled with our metabolic systems, which developed on the back of hundreds of years of evolution in energy-restricted environments, this has led to habitual eating beyond energy needs and thereby have provided a gene-environment mismatch that led to the current obesity epidemic. In conditions of excess food availability, food choices are largely determined by cognitive, social, and emotional factors.[35] Food cues with a high reward value can themselves generate powerful physiological responses to override homeostatic signals of energy availability, which fail to suppress energy intake when the reward value of a certain stimulus is too high. CNS reward centers are responsive to the effects of PYY, GLP-1, and ghrelin. Interestingly, ghrelin levels have been shown to rise in anticipation of food consumption, and levels directly correlate with reward-center activity in response to viewing food images.[114,115] In contrast, fMRI studies have demonstrated that PYY and GLP-1 inversely correlate with reward responses to food cues, and their actions suppress reward responses.[40,116]

Contributions of Components of Total Daily Energy Expenditure With Prospective Weight Change

Resting Metabolic Rate. Whether a lower-than-expected RMR contributes to weight gain is controversial. Several studies have reported that low RMR may contribute a small amount to longitudinal weight gain. The Pima Native Americans of Southwestern Arizona are perhaps the most comprehensively described population for understanding EE and body weight regulation, because they one of the most obese populations in the world. In an often-cited study, the risk of weight gain over 2 years was increased in Pima Native Americans with a lower-than-predicted RMR.[117] However, RMR explained less than 15% of weight gain over this time span. This was corroborated in a separate but similar study in which deviation from expected TDEE was weakly inversely correlated to weight change at 6-year follow-up.[118] To put this in perspective, TDEE that was 100 kcal/day lower than predicted was associated with a 0.2-kg increase in body weight/year, of which approximately 0.1 kg was FM. Therefore, lower-than-anticipated RMR and TDEE in controlled settings likely contribute a small amount to free-living weight gain.

Thermic Effect of Food. As mentioned previously in this chapter, some, but not all, studies have suggested that TEF may contribute to weight gain. In a longitudinal analysis of 290 healthy subjects, TEF (measured in a whole-room indirect calorimeter) was inversely related to percent weight change during follow-up only in subjects with a body mass index greater than 29 kg/m^2.[72] These data contrast with an analysis by Weinsier et al.,[73] in which TEF was compared between previously obese and never obese postmenopausal women. TEF was similar between these groups; women with previous obesity gained a mean of 10.9 kg over a 4-year follow-up period, while women who never had obesity maintained body weight. TEF did not correlate with 4-year weight changes.

Physical Activity Energy Expenditure. On average, PAEE decreases with aging.[74] Observational data suggest that healthy adults who engage in the lowest quintile of physical activity gained the greatest FM (1.7 ± 0.3 kg) over 1 year compared with individuals with the highest levels of physical activity.[119] In fact, those in the lowest quintile of physical activity had a 3.8-fold higher risk of gaining greater than 3% FM.[119] Just as low PAEE predicts weight gain, high PAEE predicts weight maintenance. For example, women who successfully maintain body weight over 13 years engage in 60 minutes of self-reported moderate-intensity physical activity each day.[120] Similarly, improvements in maximal aerobic capacity (as an indirect indicator of exercise engagement) has also been shown to associate with reduced odds of weight gain over 7.5 years.[121] Each additional minute performed during a graded exercise test was associated with reduced odds of gaining greater than or equal to 5 kg body weight by 14% in men and 9% in women.[121] In a community-based intervention, individuals who successfully lost weight were more likely to engage in moderate- and high-intensity exercise compared with those who gained weight.[122] For perspective, an increase of one high-intensity exercise session per week was associated with a decrease in weight of 0.54 kg in men and 0.15 kg in women.[122]

In sum, RMR that is lower than predicted may modestly contribute to weight gain. It is unlikely that TEF contributes to weight gain, although current understanding may be limited by the small number of studies that longitudinally measure both TEF and weight change. It is likely that PAEE predicts weight change to a greater extent than RMR and TEF, although this is limited by self-reported PAEE, which is less accurate than objective measures of activity.

KEY POINTS

- Several environmental and physiological factors promote weight gain. The obesogenic environments that constitute many developed countries support food choices that are largely determined by cognitive, social, and emotional factors. Furthermore, food cues alter ghrelin, peptide YY 36, and glucagon-like peptide 1 in a manner promoting increased energy intake in environments of excess food availability. In terms of total daily energy expenditure, low physical activity energy expenditure likely contributes to the development of obesity.

Physiological Responses to Weight Loss and Weight Regain

Gut Hormone Secretion in Response to Weight Loss. Generating a negative energy balance has been the mainstay of lifestyle interventions to treat overweight and obesity. However, although restricting energy intake is successful in engendering weight loss in the short-term, this is followed by a number of very powerful physiological adaptations, aimed at defending the higher body weight, that commonly result in weight regain. Weight regain following dietary and lifestyle interventions is widely reported, with weight regain in the range of a third to half of the weight loss within the first year and weight returning to baseline within 3 to 5 years from the intervention.[123,124]

A key study by Sumithran et al. investigated the effects of a 10-week very low–calorie diet (VLCD) over a 52-week follow-up period. Significant reductions in PYY, CCK, insulin, leptin, and amylin levels, combined with increased ghrelin levels, were seen at 10 weeks and persisted at 52 weeks post-VLCD.[125] These changes will promote increases in hunger, and likely energy intake. A recent study with participants who sustained 15% weight loss 1 year following a VLCD demonstrated increased ghrelin levels and hunger ratings.[126] Reduced levels of postprandial anorectic hormones (circulating GLP-1, PYY, CCK, amylin) and leptin levels, coupled with reduced satiety have also been reported in the literature.[127-129]

Hypothalamic Responses to Weight Loss. In addition to changes in the periphery, weight loss also results in adaptive changes within the appetite- and weight-controlling circuits of the hypothalamus. Within the ARC, expression of NPY and AgRP increases, whereas expression of expression of POMC decreases, leading to increased drive to eat.[130] In addition, fMRI studies have shown altered hypothalamic activity in response to dietary weight loss.[131,132]

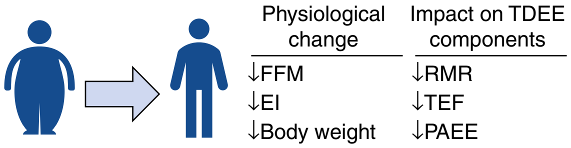

Figure 19.5 **Metabolic Alterations in Response to Weight Loss.** In a typical weight loss scenario, an individual with obesity will lose both fat mass and fat-free mass (FFM), which will lead to decreased absolute resting metabolic rate (RMR). Similarly, reduced energy intake results in lower thermic effect of food (TEF), and reduced body weight is related to decreased energy expended during activity (physical activity energy expenditure [PAEE]).

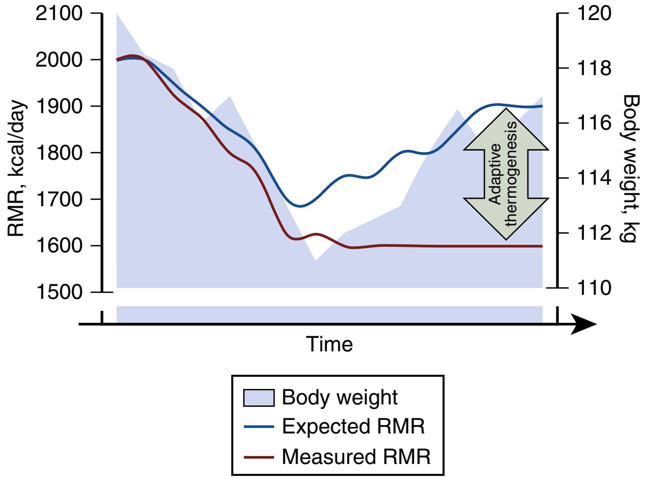

Figure 19.6 **Hypothetical Illustration of Resting Metabolic Rate (RMR) Adaptive Thermogenesis.** RMR decreases with weight loss; in some individuals, RMR may remain lower than expected after weight regain, called adaptive thermogenesis.

Changes in Components of Total Daily Energy Expenditure With Weight Loss. Weight loss through energy depletion results in a reduced sympathetic tone, as well as a reduction in thyroid hormone, which prime peripheral tissues to increase their capability for energy storage.[133] The reduction in overall body mass also results in a reduction of TDEE. Lower TDEE can be attributed to decreases in RMR due to loss of FFM and FM, TEF due to lower energy intake, and PAEE due to reduced energetic costs of activity, as summarized in Fig. 19.5.

Resting Metabolic Rate. Absolute RMR will decline as a result of lower body mass after weight loss. Some studies have suggested that RMR is lower than anticipated even after accounting for FM and FFM loss, called "adaptive thermogenesis" (Fig. 19.6).[134,135] In a highly publicized study, participants in a televised weight loss program ("The Biggest Loser") underwent RMR and body composition testing 6 years after the competition.[135] During the competition, mean weight loss was 58.3 ± 24.9 kg, and RMR decreased by approximately 600 kcal/day. At follow-up, the majority of weight lost had been regained, but RMR remained approximately 700 kcal/day below baseline and 500 kcal/day below predicted.[135] New evidence also suggests that early adaptive thermogenesis predicts weight loss during calorie restriction. Specifically, a 100 kcal/day decrease in 24-hour TDEE after 1 week of calorie restriction predicted 2.0 kg less weight loss over a 6-week inpatient weight-reduction diet among individuals with obesity.[136] Despite these rather striking results, it is important to note that adaptive thermogenesis may depend upon the amount and rate of weight loss and the duration of weight loss maintenance. For example, average RMR does not appear to differ among weight loss maintainers or normal-weight individuals who have never had obesity.[137] However, weight loss maintainers with the greatest overall weight loss were more likely to have lower-than-predicted RMR. Therefore, while some individuals may indeed have lower-than-predicted RMR, adaptive thermogenesis does not inevitably lead to weight regain.[137]

Thermic Effect of Food. Weight reduction often necessitates reduced energy intake; therefore, TEF will also decrease in accordance with this behavioral alteration. Independent of reduced energy intake, individuals with obesity may have slightly lower TEF before and after weight loss,[138] which may be due to greater suppression of hepatic gluconeogenesis, as well as lower glucose storage rate with weight loss and chronic energy intake reduction. However, TEF differences are still very small between obese and nonobese groups (8.2 ± 0.5 vs. 9.8 ± 0.5% of TDEE) and do not significantly change with weight loss (8.2 ± 0.5 vs. 8.7 ± 0.6% before and after weight loss, respectively).[138]

Physical Activity Energy Expenditure. Weight loss is associated with reduced energetic cost to move a smaller body and may therefore also relate to lower PAEE in the absence of behavioral modifications. High levels of PAEE appear to be important for maintaining a lower body weight. In a 2-year longitudinal analysis of healthy adults with no intention of weight loss, moderate-to-vigorous activity significantly increased in individuals who lost weight and decreased in individuals who gained weight.[139] Similarly, successful weight loss maintainers have higher PAEE (as measured by DLW and RMR) compared with normal-weight and obese control groups.[140] These findings have been previously corroborated by a systematic review that concluded an increased in PAEE of 1500 to 2000 kcal/week is necessary to support weight loss maintenance.[141] Therefore, high levels of PAEE are needed to maintain reduced body weight.

Insights from Bariatric Surgery. Roux-en-Y gastric bypass (RYGB) and sleeve gastrectomy (SG), the two most commonly performed bariatric operations worldwide, result in sustained weight loss and a marked change in eating behavior.[142] Following bariatric surgery, patients report reduced hunger and earlier satiety, a shift in food preference away from energy-dense foods, and changes in their sense of taste and smell.[132,143] Gut hormone secretion profiles markedly change to a favorable profile, characterized by significant rises in meal-stimulated levels of the anorectic peptides PYY, GLP-1, and OXM. Reductions in circulating ghrelin levels are also seen post–bariatric surgery.[143,144] These gut hormone secretion profiles are likely a consequence of increased EEC stimulation, which results from the anatomical changes caused by a RYGB or SG. The marked change in eating behavior following bariatric surgery, coupled with the change in gut hormone profiles, highlights the importance of these peptides in appetite and body weight regulation.

Because bariatric surgery often results in substantial weight loss, considerable changes in RMR occur and may be accompanied by adaptive thermogenesis. For example, RMR was reduced 27.3% over 12 months following SG and was approximately 200 kcal/day lower than predicted RMR using body composition.[145] However, several other investigations have not reported changes in body composition–adjusted RMR postoperatively, suggesting that adaptive thermogenesis does not occur after bariatric surgery.[146,147] Many patients also increase PAEE as a result of bariatric surgery, although approximately 25% are less active 12 months postoperatively. While there are large variations in PAEE after bariatric surgery, individuals engaging in exercise lose more weight than those who remain sedentary[148]; PAEE therefore likely plays a larger role in determining long-term success of bariatric surgery than RMR.

The Effects of Exercise on Energy Balance

The Effects of Exercise on Gut Hormone Secretion. An acute (single) bout of aerobic exercise reduces ghrelin and increases PYY, GLP-1, and pancreatic polypeptide.[149,150] The degree of this effect is likely dependent on exercise modality, as acute resistance exercise tends to elicit less pronounced alterations in gut hormone secretion.[149] Acute exercise also affects gut hormone secretion in a different manner than acute energy intake restriction. For example, a study comparing the metabolic effects of a similar energy deficit induced by either energy intake restriction or aerobic exercise reported that appetite and acyl-ghrelin levels were increased, while PYY was reduced with energy intake restriction; conversely, exercise led to a reduction in acyl-ghrelin levels and an increase in circulating PYY levels.[151]

To date, the effects of exercise on gut hormone secretion profiles in the longer term have not been characterized in depth. Some studies have suggested that acyl-ghrelin, PYY, and pancreatic polypeptide increase in response to chronic aerobic exercise interventions.[154-156] These changes theoretically support both higher hunger and satiety levels; exercise may therefore sensitize the appetite control system by balancing an increased drive to eat with improved meal-induced satiety.[149,155] These changes are particularly pronounced in response to chronic aerobic training compared with resistance training.[156] Notably, however, most of our current understanding of the appetitive effects of exercise arises from studies conducted in young, healthy, physically active males and in response to aerobic exercise. How different intensities, types, and durations of exercise regimes affect appetite in different populations such as women, older adults, or people living with obesity and other chronic health conditions remains unclear.

The Effects of Exercise on Energy Expenditure. Exercise is associated with lower risk for many chronic diseases and is important for weight loss maintenance. However, exercise may not increase TDEE in a dose-response manner. The relationship between structured exercise and components of TDEE largely depends on the type of exercise training and the population.

Resting Metabolic Rate. Exercise can be broadly categorized as resistance (strength), aerobic, or a combination of both. For the same amount of exercise, resistance exercise uses substantially less energy compared with aerobic exercise. Resistance exercise is typically more effective at increasing skeletal muscle and maintaining skeletal muscle during weight loss efforts. However, as discussed above, skeletal muscle has a low energetic cost per kilogram compared with other components of FFM (i.e., liver, heart, brain, etc.). Therefore, engaging in resistance exercise to simply increase RMR is largely ineffective. For context, healthy young males consuming sufficient calories and protein gain approximately 1.1 kg of skeletal muscle with resistance training, according to a systematic review of exercise interventions of varying duration.[157] However, this amount of skeletal muscle mass would equate to approximately 14 kcal/day to RMR (at rest).

In addition to the added caloric expenditure associated with exercise, greater SNS activity may contribute to higher RMR independently of FFM. For instance, RMR is higher in adults who regularly engage in aerobic endurance exercise compared with their sedentary counterparts.[158] This may be due in part to greater tonic SNS β-adrenergic receptor stimulation in high energy flux (i.e., high absolute levels of both energy intake and expenditure).[159] Indeed, in states of experimentally reduced energy flux among habitually

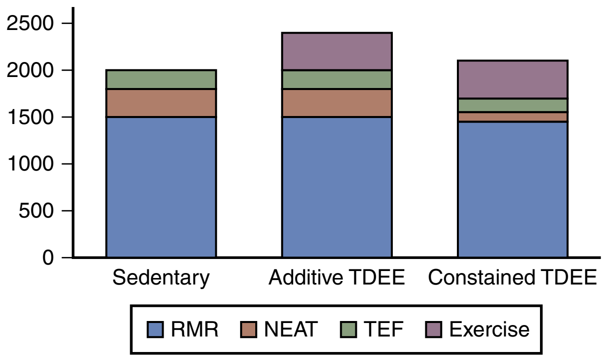

Figure 19.7 **Total Daily Energy Expenditure (TDEE) Without Exercise (Sedentary) and After Addition of Exercise Following an Additive TDEE Model and a Constrained TDEE Model.** In the additive TDEE model, TDEE increases with exercise to the same extent as the exercise. For example, an exercise session that uses 400 kcal would result in an increase of 400 kcal in TDEE in the additive model; nonexercise metabolic activity (which includes resting metabolic rate [RMR]) is not affected by exercise or physical activity variation. In the constrained TDEE model, exercise has a limited effect on TDEE and instead leads to a reduction in nonexercise activity thermogenesis (NEAT), RMR, or both. This keeps TDEE near its set point.

active older adults, there was a strong positive correlation between change in RMR and change of β-adrenergic receptor support of RMR.[159]

Physical Activity Energy Expenditure and Total Daily Energy Expenditure. A common assumption is that exercise will increase PAEE and TDEE in a linear manner, as part of an "additive" model of EE (Fig. 19.7). Although some guidelines of energy intake requirements are based on this model,[45] several exercise intervention studies have suggested that TDEE or PAEE does not increase in direct proportion to exercise EE. In fact, some studies have reported reduced NEAT in response to exercise interventions. In other words, individuals "compensate" for exercise EE by reducing other activities or increasing sedentary time outside of the exercise session. For example, an 8-week walking intervention resulted in lower NEAT among women with obesity.[160] Similar findings were reported in older men and women during 8 weeks of aerobic exercise.[161] However, it is important to note that these interventions consisted of small groups of individuals ($n \leq 13$) and may not translate to younger populations without obesity.

Compensation through reduced NEAT is not universally observed. For example, in the Dose Response to Exercise in Women study, 411 postmenopausal women with overweight or obesity were randomized to 6 months of nonexercise control or one of three exercise groups: 4, 8, or 12 kcal EE/kg body weight/week.[162,163] Individuals in the 12 kcal/kg/week group exhibited compensation (predicted weight loss: -2.7 kg; actual weight loss: –1.5 kg) that was significantly higher than groups with lower exercise loads.[163] Nevertheless, daily mean step count was not different among groups, suggesting that compensation was due to energy intake rather than NEAT reduction.[163] A more recent 6-month randomized controlled trial of 171 adults with overweight or obesity reported compensation during 8 and 12 kcal/kg/week exercise groups. While both exercise groups lost body weight, there was greater compensation in the 12 kcal/kg/week group (2.7 vs. 1.5 kg).[164] However, there were no differences in PAEE or activity patterns from accelerometry; therefore, compensation was likely due to increased energy intake related to higher appetite ratings, cravings for sweet foods, and compensatory health beliefs.[164]

Notably, early investigations observed greater weight loss in response to exercise intervention in men compared with women, which may have been due in part to compensation.[165,166] Newer investigations in which men and women are prescribed the same exercise expenditure suggest that alterations in NEAT do not differ between sexes,[164,167] although these studies are not specifically designed to investigate compensation.

Taken together, these studies suggest that PAEE does not increase in a linear fashion with the addition of structured exercise. There may be a threshold of activity where increased TDEE can be anticipated, although where the threshold lies is not clear. This phenomenon is in line with a "constrained" model of TDEE, which is informed by evolution-based principles of energy conservation. According to this model, TDEE increases linearly with PAEE at low activity levels but plateaus at higher levels to maintain TDEE within a narrow range (i.e., compensation occurs) (Fig. 19.7). This theory is supported by observations of PAEE and TDEE across five different populations from Africa and North America.[168] In an investigation of PAEE and TDEE in over 300 adults, a plateau in TDEE was observed in the upper four deciles of activity from accelerometers.[168] The constrained EE hypothesis posits that, in response to high levels of PAEE, energy allocation to essential physiological processes such as immunity, reproduction, and somatic maintenance may be reduced and contribute to lower PAEE.[169] However, because these downstream behavioral effects and subsequent compensation likely occur only at very high levels of exercise or in certain populations (i.e., older adults), the utility of the constrained model of TDEE in obesity unclear.

KEY POINTS

- Weight loss is often successful in the short term but is followed by several powerful physiological adaptations that defend body weight, which drive weight regain. Following weight loss, altered gut hormone secretion (e.g., reductions in peptide YY 36, cholecystokinin, insulin, leptin, and amylin levels and increased ghrelin levels) and hypothalamic activity (i.e., agouti-related protein and proopiomelanocortin neuronal activity), along with reduced resting metabolic rate and physical activity energy expenditure, contribute to weight regain. Exercise helps mitigate weight regain, although total daily energy expenditure may not increase in a linear fashion with structured exercise regimens due to reductions in nonexercise activity thermogenesis.

CONCLUSIONS

A set of complex physiological processes orchestrate energy intake and expenditure to regulate body weight. Key hormones such as ghrelin increase appetite and energy intake, while other hormones such as GLP-1, PYY, amylin, and CCK suppress appetite and energy intake. Together with adipose tissue–derived metabolites, these signals are integrated in the CNS to regulate eating behavior. Humans must eat to sustain TDEE, of which the largest component is RMR, and the most variable behaviorally-driven component is PAEE. BAT may also contribute to TDEE, but the effect of activated BAT on long-term energy balance is unknown. Obesogenic environments that are prevalent in developed countries promote excess energy intake and lower PAEE, and consequent long-term weight gain. However, weight loss is not as simple or straightforward as "eat less and exercise more," due to the robust and persistent adaptations in appetite and EE that cultivate weight regain.

KEY POINTS

- The gastrointestinal (GI) tract plays a key role in energy regulation. Enteroendocrine cells across the entire length of the GI tract sense ingested nutrients and through secretion of orexigenic and anorectic gut hormones transmit signals of energy availability to the brain.
- In the central nervous system, the hypothalamus plays a key role in integrating short- and long-term signals of energy availability.
- Homeostatic signals of energy availability can be overridden through powerful hedonic responses to food cues, which evolved during conditions of sparse food availability. These drive eating beyond energy requirement and in conditions of ample energy availability can result in weight gain and obesity.
- Dysregulation of fasting- and meal-stimulated gut hormone secretion is closely linked with the pathophysiology of obesity, as well as the compensatory biological responses driving weight regain following energy restriction.
- Total daily energy expenditure (TDEE) is comprised of resting metabolic rate (RMR; largely determined by body composition), the thermic effect of food (determined by meal size and macronutrient composition), and physical activity energy expenditure (PAEE; the most variable component, determined by body size and movement).
- Recent evidence suggest that brown adipose tissue (BAT) is present in a large proportion of adults. Although activated BAT generates heat increases energy expenditure, the contribution of BAT to obesity development or management is unclear.
- The obesogenic environments that constitute many developed countries support food choices that are largely determined by cognitive, social, and emotional factors (rather than physiological processes). Low PAEE (but not necessarily low RMR) also contributes to the development of obesity.
- With weight loss, altered gut hormone secretion and hypothalamic activity as well as reduced resting metabolic rate and PAEE contribute to weight regain. Exercise helps mitigate weight regain, although TDEE may not increase in a linear fashion with structured exercise regimens.

PREVALENCE OF OVERWEIGHT AND OBESITY

Due to ease of use, good correlation with body fat in a population, and association with adverse health consequences, overweight and obesity are best defined in the clinic setting using the body mass index (BMI, which is weight in kilograms divided by height in meters squared).[1] Healthy weight is a BMI of 18.5 to 24.9 kg/m^2, overweight is a BMI of 25.0 to 29.9 kg/m^2, class 1 obesity is 30.0 to 34.9 kg/m^2, class 2 obesity is 35.0 to 34.9 kg/m^2, and class 3 obesity is greater than or equal to 40.0 kg/m^2.[1] There are differences by race and ethnicity in the BMI value at which an increased risk for cardiometabolic abnormalities occurs, including high fasting glucose, low high density lipoprotein cholesterol, high triglyceride levels, and hypertension.[2] Specifically, compared with non-Hispanic Whites at a BMI of 25 kg/m^2, a similar prevalence of cardiometabolic risk factors occur in non-Hispanic Blacks at a BMI of 22.9 kg/m^2, at a BMI of 21.5 kg/m^2 for Hispanics, and a BMI of 19.6 kg/m^2 for South Asians.[2] Nonetheless, organizations including the National Institutes of Health, Centers for Disease Control, and World Health Organization have maintained the cutoffs of overweight as a BMI of 25.0 to 29.9 kg/m^2 and obesity as a BMI greater than or equal to 30.0 kg/m^2. The 2019 Behavioural Risk Factor Surveillance System (BRFSS) report indicated that 32.4% of the US population was obese, and 34.6% was overweight.[3] By race/ethnicity in the BRFSS, non-Hispanic White adults had a prevalence of obesity of 29.9%, Hispanic adults had a prevalence of 33.8%, and non-Hispanic Black adults had the highest prevalence, of 39.8%.[3] Obesity rates in adults vary by age, with those 45 to 54 years old having the highest rates, at 37.6%, and those in the 18- to 24-year age range having the lowest rate, of 18.9%.[3] Overall, obesity rates in the United States decrease with increasing education, ranging from 36.2% in those without a high school diploma or equivalent to 25% in college graduates.[3]

Although BMI correlates with body fat, its use to relate to disease is compromised by the fact that most studies classify obesity by BMI rather than body composition.[4] It is well known that BMI is not the best tool to quantify fat mass, as it does not distinguish between fat mass, fat-free mass, and lean body mass, and that individuals with similar BMIs may have different body composition. In fact, sarcopenic obesity, characterized by low lean mass with increased fat mass, could be missed using BMI alone. Those with sarcopenic obesity have a 24% increased risk for all-cause mortality compared with those with nonsarcopenic obesity.[4] Padwal et al.[5] found that both low BMI and high body fat percentage are independently associated with increased mortality.

In children, a healthy weight is defined as being between the 5th and the 85th percentile, with overweight between the 85th and 95th percentile, and obesity above the 95th percentile.[6] In youth 2 to 19 years old, in 2015 to 2016 the prevalence of obesity was 18.5%, with the lowest prevalence amongst preschoolers (13.9%) and the highest amongst adolescents (18.9%), although there was no significant difference in obesity prevalence between boys and girls.[7] However, these epidemiological data, especially when self-reported and in adults, must be interpreted with great caution. When measured objectively using data from electronic health records in the OneFlorida statewide registry, obesity rates in adults were overall 27.8% higher than those reported by BRFSS over the same time period.[8] A similar study of pediatric obesity using the OneFlorida consortium was much closer to national published data and found an overall prevalence of obesity of 16.9%, with preschoolers experiencing 9.9% obesity and adolescents 18.9%.[9]

SOCIAL AND ENVIRONMENTAL CONTRIBUTIONS TO OBESITY

In addition to individual characteristics, multiple social and environmental factors have been shown to influence obesity. A recent study examined the contribution of factors such as demographics, socioeconomics, environment, and health care on the county level variation on obesity prevalence in the United States, and is a nice summary of the contribution of each of these factors to the complex disease of obesity.[10] Demographic factors (rurality, higher percentage of females, higher percentage of individuals younger than 18 or older than 65, and a higher percentage of racial and ethnic minorities) explained approximately 45% of the variation, socioeconomic factors (e.g., household income, percentage unemployed, percentage with food insecurity) explained another third of the variation, environmental factors (access to exercise and food environment index) explained 15%, and healthcare factors (percentage uninsured and number of primary care providers) explained less than 10%.[10] With respect to the impact of the work environment on obesity, it remains to be seen to what extent the shift to working from home (and the closure of gyms) with the Covid-19 pandemic will have on obesity rates, although the shift from jobs requiring moderate to vigorous physical activity to those that are sedentary has been associated with weight gain over the last several decades.[11] Beyond the socioeconomic status evaluated above, experimentally manipulated lower social hierarchy can cause increased caloric consumption and increased anxiety, and it is plausible that this also occurs at the population level[12]

DISEASES ASSOCIATED WITH OBESITY

As reviewed elsewhere,[13,14] adipose tissue dysfunction in obesity leads to increased lipolysis and release of free fatty acids (FFAs), and perturbation of adipocytokines with high levels of leptin and proinflammatory cytokines and low adiponectin levels. In addition, impairment of adipocyte storage and lack of recruitment of new adipocytes in subcutaneous fat depots lead to expansion of the visceral fat compartment and "ectopic" fat deposition in the hepatic, pericardial, intramyocellular, and intramuscular space. This results in development of a number of obesity-related diseases, many of which are associated with higher mortality rates.[15]

KEY POINTS

- As adipose tissue expands in obesity, it becomes "dysfunctional," and resistant to insulin, resulting in impaired lipid storage in the subcutaneous adipose depot. The increased rate of lipolysis and higher serum free fatty acids promote expansion of the visceral fat compartment, with ectopic deposition of fat in various organs, contributing to development of obesity-related diseases.

Cardiovascular and Cerebrovascular Disease

Obesity is an independent risk factor for cardiovascular disease (CVD). Evidence comes from large prospective epidemiological studies like the Framingham Heart Study,[16] the Nurses' Health Study,[17] and the Manitoba study.[18] Obesity is not only associated with increased risk of cardiovascular (CV) morbidity and mortality, but also with shorter longevity, and a greater proportion of life lived with CVD, when compared with individuals with normal BMI.[19] In addition, obesity contributes to higher CV risk through hypertension, atherogenic dyslipidemia, type 2 diabetes, and nonalcoholic fatty liver disease (NAFLD), as detailed below.

Hypertension. In large cohort studies[20-23] the prevalence of hypertension in both men and women increased with elevated BMI. In one study, the prevalence of hypertension was five times higher in adults with a BMI greater than 30 kg/m^2 compared with those with a BMI less than 20 kg/m^2.[20] In the Framingham study population of 5209 men and women, systolic blood pressure (BP) increased by 4 mm Hg for each 4.5 kg of increased weight.[23] In the Nurses' Health Study, the strongest risk factor for developing hypertension was an elevated BMI, with women with obesity having a 4.7 times higher incidence of hypertension than did women with a BMI less than 23 kg/m^2.[22] Moreover, subjects who were overweight or obese as children and remained in this weight category as adults had a 2.7 higher relative risk of developing high BP[24] and 1.7 times higher risk for carotid artery atherosclerosis (increased thickness of the carotid artery intima media).[24]

Weight gain or loss of 5 to 10 kg increased or reduced, respectively, the risk of high BP in women by 74% or 15%.[21] In general, the magnitude of weight loss correlates with a reduction in BP. Body weight loss of 5.1 kg after diet and exercise program reduced systolic BP by 4.4 mm Hg and diastolic BP by 3.5 mm Hg in a metaanalysis of 25 studies.[25] Long-term remission of hypertension with no need for BP medications was reported in approximately 38.2% after gastric bypass surgery.[26]

Dyslipidemia. The hallmark of obesity associated dyslipidemia is low high-density lipoprotein (HDL) cholesterol (HDL-C) levels.[27] In addition to decreased HDL, obesity is associated with increased triglycerides, total cholesterol, total low-density lipoprotein (LDL), and small, atherogenic, dense LDL, which is one of the drivers of increased CVD. Individuals with obesity since childhood who remain in the obese category as adults have a two to threee times higher risk of reduced HDL-C, elevated LDL-C levels, and increased triglyceride levels.[24]

Several mechanisms may contribute to low plasma HDL-C in obesity: 1) a relative lack of lipoprotein lipase activity, resulting in an increase in triglyceride-rich lipoproteins and reduction in HDL-C formation, 2) increased hydrolysis of triglyceride-rich HDL by hepatic lipase, and 3) lower levels of adiponectin, which has been suggested to regulate cholesterol efflux capacity of HDL, particle size, and composition.[27,28]

Coronary Artery Disease. Numerous observational studies show increased CVD disease risk with higher BMI,[13,19] with some studies identifying BMI as independent of other cardiometabolic risk factors.[29] In a metaanalysis of ten studies, central adiposity, as reflected by a high waist circumference or high waist-to-hip ratio, was a better indicator of CV risk factors (including hypertension, diabetes, and dyslipidemia) than BMI alone.[30]

In two large prospective studies, excess weight (BMI >30 kg/m^2) doubled the risk of coronary artery disease (CAD; relative risk 2.1 in men and 2.5 in women).[31] Obesity has also been associated with occurrence at a younger age of first non–ST-segment elevation myocardial infarction compared with lean subjects.[32] This was noted to be 12 years earlier in patients with severe obesity (BMI greater than 40 kg/m^2).[32] A recent large study (n = 3884, 58% male) among patients undergoing coronary computed tomography angiography (CTA) found an increased burden of CAD for individuals with BMI greater than 25 kg/m^2 compared with those with normal BMI.[33]

Metabolically healthy obesity (MHO), defined as obesity with normal BP, glucose, and lipid metabolism, occurs in 10% to 20% of obese subjects and has been associated with better cardiorespiratory fitness and significantly less risk of CV events and all-cause CV mortality compared with individuals with metabolically unhealthy obesity (MUO).[29] Patients with MHO exhibit less CAD than those with MUO, as measured by coronary CTA.[33,34] However, CV risk in MHO is higher than in lean, metabolically healthy individuals.[29] Moreover, in long-term follow-up studies (>8–10 years) almost half of those with MHO will convert to a metabolically unhealthy phenotype, with at least one metabolic abnormality.[13,35,36]

Modest weight loss (5%–10%) has been associated with significant improvement in CV risk factors.[37] The greater weight loss achieved with bariatric surgery (>20%) is associated with a reduced number of CV deaths (adjusted hazard ratio of 0.47 after bariatric surgery).[38]

Heart Failure. Obesity is associated with structural and functional changes of the heart that promote risk of heart failure (HF). Framingham Heart Study data indicate that a 1-kg/m^2 rise in BMI increases risk of heart failure by approximately 5% to 7%.[39] Conversely, the risk of HF declines with weight loss, and the greater weight loss achieved with bariatric surgery reduces HF risk more than usual care.[40] The most common form of obesity-associated HF, which has increased in incidence in the past decade, is characterized by impaired diastolic function and preserved left ventricular ejection fraction (pEF) in the absence of major coronary artery, valvular, or arrhythmic disease. This is referred to as HFpEF, or diastolic HF.[4]

There are multiple mechanisms involved in development of obesity-related cardiomyopathy and HF.[41] Elevated inflammatory cytokines[42] (TNF-α, IL-6, C-reactive protein), and trophic hormones (insulin and leptin), combined with activation of the renin-angiotensin-aldosterone system, promote cardiac fibrosis and endothelial dysfunction. Accumulation of intramyocardial lipid and excess myocardial ceramide production[43] contribute to diastolic dysfunction, increased cardiac output, and increased BP. Atherogenic dyslipidemia and intertwined comorbidities including diabetes mellitus, sleep apnea, pulmonary hypertension,[44] and obesity hypoventilation syndrome also contribute to HF.

Despite an increased risk of HF with excess adiposity/higher BMI, a number of studies report a protective effect of higher BMI on survival and other clinical outcomes in individuals with already established HF. Whether this phenomenon, termed "the obesity paradox,"[4,13,41] reflects an actual protective effect of excess body fat on HF-associated mortality remains a matter of debate. Potential explanations for the obesity paradox include: 1) comparison to unhealthy thinner patients in end-stage disease states, 2) statistical confounding, 3) survival bias, and/or lead time bias, and 4) greater body energy stores for periods of time when food intake is compromised. The presence of other comorbidities and possible treatment differences between BMI groups may also contribute.[4,41] Despite the obesity paradox, a number of studies have shown benefits of weight loss on outcomes of HF, including improvement in left ventricular function[45] and a more than 40% reduction in the risk of HF after bariatric surgery.[46]

Stroke. Obesity, as a chronic proinflammatory, prothrombotic state, is associated with increased risk of stroke. While this may be attributable in part to the higher prevalence of hypertension, dyslipidemia, and type 2 diabetes mellitus in obese individuals, there is evidence for an independent association between excess adiposity and stroke. In a large prospective cohort of male physicians with 12.5 years' follow-up, each 1-unit increase in BMI was associated with a 4% increase in risk of ischemic stroke (independent of other variables such as hypertension, hyperlipidemia, and diabetes) and 6% for hemorrhagic stroke.[47] Central/abdominal adiposity with high waist circumference or waist-to-hip ratio, in comparison with BMI alone, has been more strongly associated with increased risk of stroke and transient ischemic attack, independent of other vascular risk factors.[48]

KEY POINTS

- Obesity is an independent risk factor for cardiovascular disease and is associated with a 4- to 5-fold increased risk of hypertension, a 2-fold higher risk of coronary artery disease, and higher risk of heart failure with preserved left ventricular ejection fraction. Central adiposity also increases the risk of ischemic stroke and transient ischemic attack.

Type 2 Diabetes Mellitus

In the last decades the increasing prevalence of obesity has been accompanied by an increased incidence of metabolic syndrome and type 2 diabetes mellitus (T2DM). Among American adults, 1 in 3 have prediabetes, and 1 in 10 have T2DM.[49] Central obesity predicts future development of T2DM, with insulin resistance being the earliest abnormality seen in both prediabetes and overt T2DM.[14] Adipose tissue plays an important role in maintenance of total body glucose homeostasis by regulating the release of FFAs from stored triglycerides and through the production of adipocytokines that influence insulin sensitivity in muscle and liver.[14] In the progression from normoglycemia to impaired glucose tolerance to T2DM, insulin secretion increases to compensate for insulin resistance; however, despite high concentrations, insulin secretion becomes insufficient due to presence of β cell dysfunction, and eventually β cell failure.[50,51] The imbalance between insulin sensitivity, insulin secretion, and insulin action leads to an increase in both fasting and postprandial glucose concentrations.[52] The high levels of peripheral insulin concentrations are also, in part, due to decreased hepatic insulin clearance in the setting of obesity, ectopic fat deposition and NAFLD.[51,53]

Obesity management and weight loss can prevent, delay, and even reverse diabetes.[54] A 5.5% weight loss reduces the risk of conversion from prediabetes to diabetes by 58%,[55] and loss of 20% to 25% of body weight with bariatric surgery can result in complete remission of diabetes.[56,57] See Chapters 40 and 27 for in-depth discussion of pathophysiology of diabetes and effects of bariatric surgery to improve outcomes.

Nonalcoholic Fatty Liver Disease

The hepatic manifestation of obesity and metabolic syndrome, NAFLD, encompasses a spectrum of disorders characterized by hepatic steatosis (liver fat content ≥5% on biopsy) in the absence of significant alcohol consumption (<20 g per day) or other causes of liver disease.[58] NAFLD is associated with a 2-fold higher risk for incident diabetes and increased CV morbidity and mortality.[51,59] Its more severe form, nonalcoholic steatohepatitis (NASH) is characterized by the presence of inflammation, hepatocyte injury (ballooning and hepatocyte necroinflammation), and often fibrosis, which can lead to liver cirrhosis and hepatocellular carcinoma.[60] NASH is currently the second leading cause of liver transplantation in the United States,[58,60] and has an estimated global prevalence of 3.5%.[61]

Recent metaanalyses estimate the global prevalence of NAFLD to be 25% in the general population[61] and 56% in patients with T2DM.[62] As assessed by liver biopsy at the time of bariatric surgery, NAFLD was present in 79% to 83% of patients with morbid obesity.[63] Using the gold standard magnetic resonance spectroscopy,[64] the prevalence of NAFLD is 34% in general population and 70% in adults with T2DM.[65-67] Given the increased risk of liver fibrosis in patients with T2DM,[67] the American Diabetes Association recommended in 2019 that patients with T2DM and elevated plasma alanine aminotransferase or steatosis on imaging be evaluated for NASH and presence of liver fibrosis.[68] The purpose of screening is to identify patients with liver fibrosis and advise interventions that can potentially prevent the progression to decompensated cirrhosis.

Hepatic lipid storage in NAFLD is driven by increased FFA availability from unrestrained lipolysis in dysfunctional adipose tissue (lipotoxicity).[59] In addition, hyperinsulinemia (through activation of SREBP1c) and hyperglycemia (through ChREBP) will further promote hepatic triglyceride accumulation. Genetic predisposition may also play a role in steatosis. In genome-wide association studies, the rs738409 polymorphism in the patatin-like phospholipase 3 (*PNPLA3*) gene, found in 30% to 50% of individuals,[69] and the rs58542926 polymorphism in the transmembrane 6 superfamily member 2 (*TM6SP2*) gene[70] have been associated with greater liver triglyceride accumulation and worse prognosis. The progression of NAFLD to NASH has been linked to a number of factors, including insulin resistance[53] and abnormal mitochondrial function, with an early compensatory increase in mitochondrial oxidative capacity in NAFLD and loss of this hepatic mitochondrial adaptation or "flexibility" in NASH.[71,72]

Substantial improvement in NAFLD and histologic outcomes of NASH, including fibrosis, are directly proportional with the magnitude of weight loss. Weight loss of 5% to 7% decreases steatosis, with 8% to 10% weight loss needed to reverse steatohepatitis,[73,74] and greater than or equal to 10% weight reduction may also improve fibrosis.[73] Bariatric surgery–induced weight loss of greater than or equal to 20% improves steatosis in 90% of patients, results in resolution of NASH in 70% to 90%, and improves fibrosis in 50% to 65% of patients.[75,76]

KEY POINTS

- The hallmark of obesity-associated dyslipidemia is low high-density lipoprotein cholesterol. The increasing prevalence of metabolic syndrome, prediabetes, and diabetes parallels that of obesity. Similarly, nonalcoholic fatty liver disease (NAFLD), the hepatic manifestation of metabolic syndrome, is associated with a 2-fold higher risk for incident diabetes and increased cardiovascular morbidity and mortality. The more severe form of NAFLD, nonalcoholic steatohepatitis, is currently the second leading cause of liver transplantation in the United States.

Gastrointestinal Complications

In addition to NAFLD, obesity is a risk factor for a number of other gastrointestinal complications, including gastroesophageal reflux disease (GERD), pancreatitis, and gallstones. The prevalence of GERD in the general population is 8% to 33%, but this increases to 73% in the severely obese.[77] Chronic esophageal acid exposure can progress to Barrett's esophagus and esophageal adenocarcinoma.[78]

Acute pancreatitis can range from mild to severe and have an acute onset. Multiple large prospective population-based studies and meta-analyses have demonstrated that BMI is an independent predictor of severity and mortality from acute pancreatitis, with visceral adipose tissue content an additional important prognostic indicator for severity.[79] Mechanisms linking adiposity to acute pancreatitis include increased release of proinflammatory cytokines and fatty acids, and reduced levels of adiponectin.[80]

Obesity has a strong association with gallstone diseases. The incidence of cholelithiasis, cholecystitis, and cholesterolosis are all greater in subjects with obesity compared with normal-weight individuals. Mechanisms include supersaturated bile, gall bladder dysmotility, dyslipidemia, and hyperinsulinemia.[78]

It has recently been appreciated that bile acids regulate glucose homeostasis by activating the farnesoid X receptor (FXR). In the liver, FXR increases hepatic triglyceride clearance and suppresses gluconeogenesis. Activation of FXR in pancreatic β-cells increases calcium influx (by inhibiting plasma membrane potassium channels), resulting in greater glucose-stimulated insulin secretion. The increase in circulating bile acids in response to meal intake in subjects with obesity intake appears to be suppressed in some, but not all, studies. There is also evidence that the composition of the bile acids is altered in obesity. Thus, as gall bladder disease progresses in obesity, and the composition of bile acids is altered, dysfunction in the gland may contribute to worsening of insulin resistance.[81,82]

Cancer

The association between excess body weight and death from cancer has been recognized for approximately five decades. There is strong evidence that being overweight or obese in adulthood increases the risk of cancer of the mouth, pharynx, larynx, esophagus, stomach, pancreas, gall bladder, liver, kidney, colon, rectum, ovary, and prostate.[83] In a recent population cohort study of over 3.5 million people with a mean follow-up time of approximately 13 years, obesity (BMI 30.0–34.9 kg/m^2) increased the hazard ratio for cancer of the liver (1.66 [1.37–2.02]), uterus (2.08 [1.66–2.61]), and kidney (1.77 [1.46–2.14]) compared with normal-weight individuals (BMI 22.5–24.9 kg/m^2) who never smoked.[84] Hazard ratios for a number of additional cancers were also significantly increased. One mechanism linking adiposity to cancer risk is insulin resistance, resulting in elevated insulin acting through the insulin-like growth factor receptor to promote tumor cell growth.[85] Increased release of adipokines, inflammation, and oxidative stress in obesity also play a role. There is evidence that tumor cells may actively alter the function of surrounding adipocytes to promote secretion of lipids and adipokines that support tumor growth.[86]

In postmenopausal women there is a strong causal relationship between obesity and estrogen receptor positive breast cancer, attributed to estrogen release from adipose tissue. In contrast, there is an inverse relationship between breast cancer incidence and BMI in premenopausal women, which has been partly attributed to higher rates of amenorrhea in obese premenopausal women resulting in lower decreased circulating estrogen.[87]

Significant weight loss can reduce cancer risk. Following bariatric surgery there is a 33% decrease in the incidence of cancer (particularly in obesity-related cancers, such as colon, endometrial, and postmenopausal breast cancer) compared with a nonsurgical control.[88]

Reproductive Health

Polycystic ovarian syndrome (PCOS) is the most common endocrinopathy affecting reproductive-age women (see Chapter 124). Approximately 50% of women with PCOS are overweight or obese, demonstrating that excess weight is not necessary for PCOS to occur. However, obesity augments the adverse metabolic and reproductive outcomes of PCOS.[89] Women with PCOS are more likely to have increased visceral adiposity and obesity-induced insulin resistance, resulting in elevated insulin levels that sensitize thecal cells to luteinizing hormone, which results in increased androgen production.[90]

Obesity reduces fertility in women.[91,92] Time to pregnancy is also increased in couples where both the man and woman are obese.[93] Oligo- and anovulation are observed more frequently in overweight and obese women. Changes in the endometrium, oocyte, and embryo have also been reported.[94] Overweight and obese men have higher rates of oligo- and azoospermia, erectile dysfunction, and altered hypothalamic-pituitary-gonadal axis function.[94]

Maternal obesity during pregnancy is associated with increased rates of cesarean section and medical complications for both the mother and fetus. Pregnant women with obesity are at increased risk for gestational diabetes (see Chapter 34), preeclampsia, and hypertension. The health risks for babies of mothers with obesity include an increase in preterm birth, large-for-gestational-age birth, and congenital malformations including neural tube defect and CV anomaly. Maternal obesity also increases the risk for stillbirth, miscarriage, and fetal death.[95]

Obstructive Sleep Apnea

The prevalence of obstructive sleep apnea in obese individuals is 30%, and there is a strong association with visceral adiposity.[96] Mechanisms include fat deposition in the lateral fat pads and base of the tongue leading to narrowing of the airway, compression of the chest and abdominal wall, and a more collapsible trachea. Lung volumes can be reduced with obesity, and respiratory control may be altered.[97] Conversely, insufficient sleep and poor sleep quality are risk factors for development of obesity and type 2 diabetes.[98]

TABLE 20.1 **Weight-Loss Treatment Guidelines**

Treatment	BODY MASS INDEX (kg/m^2)				
	25–26.9	27–29.9	30–34.9	35–39.9	≥40
Diet, physical activity, and behavior therapy	Yes	Yes	Yes	Yes	Yes
Pharmacotherapy		In patients with obesity-related disease	Yes	Yes	Yes
Surgery				In patients with obesity-related disease	Yes

(Modified from Eckel RH. Clinical practice. Nonsurgical management of obesity in adults. *N Engl J Med.* 358:1941–1950, 2008; and Wadden TA, Butryn ML, Wilson C. Lifestyle modification for the management of obesity. *Gastroenterology.* 2007;132:2226–2238.)

Osteoarthritis

Obesity is a primary risk factor for development of osteoarthritis of the knee. In a metaanalysis of new-onset knee pain, 24.6% of cases were related to overweight or obesity.[99] Obesity increases mechanical stress on load-bearing joints and contributes to a higher prevalence of osteoarthritis in non–weight-bearing areas through an increase in proinflammatory cytokines produced by excess adipose tissue.[100]

Cognitive Dysfunction and Alzheimer Disease

Overweight and obesity in midlife are strongly associated with increased risk for cognitive decline. Abdominal obesity may be a better predictor of cognitive decline than overall adiposity. Obesity in late life is not associated with dementia risk. This obesity paradox is attributed to weight loss in the preclinical stage of dementia, as BMI starts to decline 6 to 10 years prior to dementia diagnosis.[101] Total brain volume and gray matter volumes are reduced in middle-aged subjects with obesity.[102,103]

Oxidative stress, inflammation, and insulin resistance in the brain have all been implicated as mechanisms altering neuronal function to impact cognition.[101,104,105] Obesity-associated inflammation and oxidative stress in the brain may result in a vicious cycle that leads to an impaired ability to regulate subsequent caloric intake, promoting further weight gain.[104,105]

THERAPY FOR OBESITY

Many factors can influence body weight; therefore, a thorough medical history and evaluation are required before therapy is initiated. The assessment of overweight and obese patients should include: 1) personal and family medical history, 2) consideration of medications that contribute to weight gain, such as corticosteroids, antidiabetic agents (insulin, thiazoladinediones, and some sulfonylureas), antidepressants and antipsychotic agents, and antihistamines and progestin-based contraceptives, 3) previous approaches to weight reduction, 4) patterns of food intake, including binge eating, and (5) physical activity levels. Measurement of waist circumference and evaluation of BP, blood glucose, lipids, and liver function should be performed. Treatment of coexisting conditions should follow standard guidelines. The patient's readiness for weight loss can be addressed with instruments such as the S-Weight and P-Weight questionaires,[106] which are based on the transtheoretical model that includes stages in the process of change. The absence of readiness should not preclude communication between provider and patient concerning the importance of weight reduction, as evidence that readiness predicts successful weight loss is not strong.[107]

The goal of weight loss is to improve patient health and quality of life by reducing and maintaining a lower body weight. Prevention of additional weight gain in individuals who cannot lose weight also provides benefit. The treatment options for weight loss include comprehensive lifestyle intervention (diet, exercise, and behavioral modification), pharmacotherapy, endoscopic treatment, and bariatric surgery (Chapter 27). Table 20.1 presents a summary of the treatment guidelines originally put forth by the National Heart, Lung, and Blood Institute,[108] which remain consistent with current recommendations of medical associations.[1,109,110]

Lifestyle Intervention

The combination of reduced-calorie diet and increased physical activity is the primary recommendation to achieve weight loss. High-intensity behavioral counseling with 14 or more visits over 6 months is required for the best outcomes. Behavioral therapy provides the techniques needed to adopt dietary and physical activity recommendations, which should include recording food intake, activity, and weight on a regular basis. Weekly meetings with a trained interventionist should include a review of progress, goal setting, and instructions for problem solving. Referring patients to a high-intensity community program such as the YMCA, which offers a version of the Diabetes Prevention program, can be a viable option. Commercial weight loss programs such as Weight Watchers and Jenny Craig have also been shown in the peer review literature to be effective. Telephone- and web-based interventions that include personalized provider feedback can in some cases be as effective as in-person counseling, at reduced cost. Less intensive lifestyle counseling can be an option to prevent weight gain in patients at low risk for concomitant disease.

Weight regain is common following completion of lifestyle intervention programs. Continued support (every other week or monthly) is useful in preventing weight regain but is often difficult to implement and maintain.[111]

Diet. Common weight-loss prescriptions target a reduction in dietary intake of 500 kcal/day and increase energy expenditure through exercise (see later) to achieve a weight loss of one to two pounds per week. To achieve the reduction in energy intake, the subject can be instructed to target consumption at 1,200 to 1,500 kcal/day for women and 1,500 to 1,800 kcal/day for men (varying levels by the individual's body weight), which can be assumed to produce a deficit compared with their habitual intake. The intake recommendation can be more specifically tailored using a number of different formulas that incorporate sex, weight, and age. Alternatively, subjects can be advised to avoid specific types of foods, which can lead to voluntary reductions in caloric intake.

TABLE 20.2 **Intermittent Fasting Approaches**

DIET	FEEDING DAY Calories Allowed	FASTING DAY Calories Allowed	FAST DAYS PER WEEK
Alternate-day fasting	*Ad libitum*	None	3–4
Alternate-day modified fasting	*Ad libitum*	25% over a 2-hour period	3–4
5:2 diet	*Ad libitum*	25% at any time	2 (sometimes consecutive)
Time-restricted feeding	*Ad libitum*	100% over a 10-hour period	7

(Adapted from Hoddy KK, Marlatt KL, Cetinkaya H, et al. Intermittent fasting and metabolic health: from religious fast to time-restricted feeding. *Obesity (Silver Spring)*. 2020;28:S29–S37.)

A number of diets that differ by macronutrient content have been tested and proven efficacious for weight loss including low-fat, low-carbohydrate, high-protein, low–glycemic index, and Mediterranean-style prescriptions. These diets work by reducing the number of calories consumed. For example, low-fat and low–glycemic index diets reduce the caloric density of foods ingested. Low-carbohydrate diets reduce food choice to decrease consumption, and high-protein diets have prolonged satiating effects. Given the large and varied number of options the patient and provider can choose, a diet that will result in the best adherence should be chosen, as this is the most important factor in success.[112]

Over the past several years there has been increased interest in the use of very low calorie ketogenic diets (VLCKDs) for weight loss. Very low calorie diets (VLCDs) provide 400 to 800 kcal/day, often in a liquid or bar product containing large amounts of dietary protein. To be classified as ketogenic, the diet can provide no more than 30 to 50 g/day of carbohydrate. VLCDs and VLCKDs can be used prior to bariatric surgery to reduce liver volume, and there is also some evidence for a reduction in the risk of complications following surgery.[113] Trials in non–bariatric surgery populations suggest that VLCKDs can safely induce substantial weight loss in the short term (4–6 weeks), with subjects reporting less hunger.[114] However, over the longer term, weight loss with VLCKDs is similar to that of diets with higher quantities of carbohydrate, and long-term adherence is difficult to maintain.[112]

Intermittent fasting has recently emerged as a new approach to alter caloric intake. There are many variations of intermittent fasting, including alternate-day fasting (ADF), alternate-day modified fasting (ADMF), the 5:2 diet, and time-restricted feeding (TRF). All of these interventions utilize prolonged periods of fasting (Table 20.2), resulting in variable amounts of weight loss. ADF and TRF do not restrict calories but may indirectly result in reduced energy intake. ADMF and 5:2 diets utilize very low-calorie diets. Intermittent fasting appears to have additional health benefits beyond weight loss, including decreased fasting insulin. Compliance is comparable to standard diets, and there is heterogeneity in response, suggesting that a personalized approach may be beneficial.[115]

Exercise. Increased physical activity combined with dietary restriction is central to all weight-loss programs. Exercise provides CV benefits, prevents loss of muscle mass during weight loss, reduces visceral fat, and promotes better dietary adherence through improved mood.[116,117] Exercise in the absence of caloric restriction can result in modest weight loss, but requires high intensity at a frequency of three to five times per week. Such exercise is difficult for most people with obesity to maintain for the long periods of time necessary to achieve significant weight loss.[116]

Recommendations for increasing physical activity include programmed aerobic exercise activities such as fast walking, running, and swimming. For substantial health benefits, adults are recommended to complete at least 150 minutes a week of moderate-intensity physical activity, or 75 minutes of vigorous-intensity aerobic activity, in episodes of at least 10 minutes throughout the week. For more substantial health benefits, these recommendations should be doubled.[118] Lifestyle modifications that increase "steps," such as parking further away from store entrances and taking stairs instead of elevators, also have modest effects.[116] Resistance training (lifting weights or working with elastic bands) improves body composition, with modest weight loss, and can be prescribed for subjects who have difficulty participating in aerobic activities.[119] The combination of aerobic and resistance training provides both CV and body composition benefits during weight loss.

There is good evidence that increased amounts of sedentary time, measured as daily sitting time, television viewing, or low counts on an activity monitor such as an accelerometer, are associated with increased risk for incident CVD and T2DM, and for all-cause CVD mortality. The effect of interventions to decrease sedentary behavior and the confounding role of BMI remain to be fully elucidated.[120]

Pharmacotherapy

Antiobesity medications are recommended for patients who fail to achieve clinically significant weight loss (≥5% of baseline weight) after 6 months of lifestyle interventions.[1,109] These should be prescribed as part of a plan that continues to include lifestyle interventions. Use of weight-loss drugs should be considered long-term, and no completely risk-free formulations are available. Thus, a balance must be achieved between risk and efficacy in a highly heterogeneous group of individuals with a wide range of risk factors for significant disease.

Pharmacologic treatment of overweight and obesity has been practiced for at least 80 years, and many formulations have been withdrawn from the market for safety reasons. Early weight-loss pharmacotherapy was based on the short-term use of amphetamine or structurally similar compounds. Currently, phentermine and diethylpropion remain approved for short-term use (12 weeks) in the United States. These drugs act primarily by inhibiting reuptake of norepinephrine and dopamine at nerve endings, which enhances *satiation* (level of fullness during consumption of a meal) and *satiety* (level of hunger after consumption of a meal).[121]

Anorexiants that modulate serotonin levels in the brain include fenfluramine, its isomer dexfenfluramine, and sibutramine. Fenfluramine and dexfenfluramine were removed from the market in 1997 due to increased incidence of valvular heart disease. Sibutramine, a serotonin and norepinephrine uptake inhibitor approved in 1997, was withdrawn in 2010 due to increased risk of major CV events.[121] Lorcaserin, a selective serotonin 5-HT2c receptor agonist approved in the United States in 2012, was voluntarily recalled in 2020 due an increased risk of certain cancers.[122]

Four medications and one device are currently approved for long-term weight loss. These are discussed later and summarized in Table 20.3.

Orlistat. A synthetic derivative of lipstatin (from *Streptomyces toxytricini*), orlistat inhibits gastric and pancreatic lipases, enzymes critical

TABLE 20.3 **US Food and Drug Administration—Approved Weight Loss Treatments**

Name	Mechanism of Action	Term of Use
Phentermine	Sympathomimetic	Short-term (3 months)
Diethylpropion	Sympathomimetic	Short-term (3 months)
Orlistat	Intestinal lipase inhibitor	Long-term
Phentermine-topiramate	Combination sympathomimetic and carbonic anhydrase inhibitor	Long-term
Bupropion-naltexone	Combination dopamine/norepinephrine reuptake inhibitor and mu-opioid receptor antagonist	Long-term
Liraglutide	Glucagon-like peptide-1 receptor agonist	Long-term
Gelesis100	Absorbent hydrogel in stomach	Long-term

for the digestion and absorption of fat from the gastrointestinal tract. Inhibition of lipases causes a reduction in the absorption of fat, resulting in increased excretion of triglycerides in feces. In a 2-year randomized crossover study of 688 obese individuals (BMI ~36 kg/m^2, weight ~100 kg), orlistat, 120 mg three times daily, caused a 10.2% decrease in initial body weight after the first year of treatment compared with a 6.1% decrease in the placebo group.[123] Several metaanalyses have shown favorable effects of orlistat on weight loss and weight maintenance. In addition, pooled data show significant overall beneficial effects of orlistat on cholesterol, triglycerides, BP, and hemoglobin A1c. Orlistat is currently available as a prescription medication (120 mg, Xenical) and a US Food and Drug Administration (FDA)-approved over-the-counter preparation marketed under the trade name Alli (60 mg).

Side effects of orlistat, which is not absorbed from the intestinal tract, are limited to gastrointestinal symptoms (fatty/oily stool, fecal urgency and incontinence, flatulence). A small but significant reduction in fat-soluble vitamin uptake can occur, and multivitamin supplementation is recommended.

Phentermine-Topiramate. Four fixed-dose combinations of phentermine plus topiramate were approved in 2012 for prescription use in the United States. The dose combinations are: starting (3.75 mg phentermine plus 23 mg topiramate); recommended (7.5 mg phentermine plus 46 mg topiramate); titration (11.25 mg phentermine plus 69 mg topiramate); and top (15 mg phentermine plus 92 mg topiramate). Both phentermine and topiramate alone cause weight loss and are available as generics. Topiramate has several actions, including blocking sodium and L-type calcium channels and inhibiting carbonic anhydrase activity, although its precise mechanism for inhibiting appetite is not well understood. Similarly, the weight-loss mechanism of the combination is not understood but is attributed to a reduction in appetite. In clinical studies, phentermine-topiramate reduced body weight by 10.6%, 8.4%, and 5.1% with 15/92 mg, 7.5/46 mg, and 3.75/23 mg, respectively ($P < 0.0001$).[124]

Phentermine-topiramate side effects include tachycardia, suicidal ideation, vision changes, mood changes, insomnia, paraesthesia, dizziness, confusion, dysgusia, constipation, and dry mouth. Topiramate is a recognized teratogen, at least at the higher doses used for the treatment of epilepsy. The combination of phentermine-topiramate carries a warning of birth defects (cleft lip and palate) in the offspring of pregnant women taking the combination therapy. Pregnant women should not take the drug, nor should women who are trying to conceive or who are at risk for becoming pregnant.[125]

Bupropion-Naltrexone. Bupropion, an atypical antidepressant, is an inhibitor of dopamine and norepinephrine uptake. Naltrexone is an opioid receptor antagonist approved for treatment of alcoholism and opioid addition. The combination of bupropion and naltrexone was approved in 2014, with a titrated total daily dose of bupropion 360 mg/naltrexone 32 mg. Weight loss following 52 weeks of treatment ranges between 2.5% and 5.2% of initial body weight. The most common side effects are nausea, constipation, headache, dizziness, insomnia, dry mouth, and diarrhea. There is no potential for abuse with this treatment.[126,127]

Liraglutide. Originally approved in 2010 for treatment of T2DM, this glucagon-like peptide-1 (GLP-1) analog received approval as a weight-loss modality by the FDA in 2014. Dosing is titrated to 1.8 mg/day for glycemic control and to 3.0 mg/day for weight loss. Substantial work in rodent models has shown that physiologic release of GLP-1 from the gut in response to nutritive molecules signals to the brain via vagal afferents. In contrast, GLP-1 analogs act directly in the brain to inhibit appetite.[128] Three large clinical trials demonstrate weight loss of 4.0% to 6.1% over 56 weeks.[129] Liraglutide treatment produces significant reductions in BP and triglycerides. A significant 13% reduction in major adverse CV outcomes in obese adults with type 2 diabetes was achieved with 1.8 mg/day liraglutide in the LEADER trial, which was specifically designed to assess CV outcomes.[129] The most common side effects of liraglutide are nausea, vomiting, and abdominal pain.

Gelesis100. This device for weight loss was approved by the FDA in 2019 for adults with a BMI of 25 to 40 kg/m^2, with or without comorbidities. Gelesis100 is a hydrogel matrix that is ingested as three capsules (2.25 g/dose) with 500 mL of water 20 to 30 minutes prior to lunch or dinner. The hydrogel absorbs water and expands to fill approximately one fourth of stomach volume to promote fullness. In a 6-month randomized double-blind placebo-controlled trial in 436 adults, Gelesis100 induced a significant weight loss of 6.4% versus 4.4% in the placebo group. Of note, 58.6% of subjects taking Gelesis100 lost greater than 5% of baseline weight compared with 42.2% of controls. Side effects were abdominal distension, infrequent bowel movements, and dyspepsia.[130] Gelesis100 is contraindicated in pregnancy and individuals with gastrointestinal reflux diseases or other conditions that affect gastrointestinal transit and motility.

Diabetes Treatments that Promote Weight Loss. Metformin suppresses gluconeogenesis and increases peripheral insulin sensitivity. In the Diabetes Prevention Trial, metformin without lifestyle intervention resulted in a 2-kg weight loss that was maintained during follow-up.[131] Several mechanisms have been suggested for how metformin may induce weight loss, including its ability to activate adenosine monophosphate–activated protein kinase. Most recently it has been demonstrated that metformin increases circulating levels of GDF15, which acts in the hindbrain to suppress food intake.[132] Pramlintide, an analog of the pancreatic hormone amylin, regulates postprandial glucose control. Pramlintide reduces food intake through actions in the brain, resulting in weight loss of approximately 6% at 1-year follow-up.[133]

Sodium-glucose transport-2 (SGLT2) inhibitors act in the kidney to reduce glucose reabsorption, resulting in lower plasma glucose levels. In clinical trials in subjects with T2DM and phase II trials in obese subjects without diabetes, SGLT2 inhibitors produce approximately 2 to 3 kg of weight loss. The mechanism is thought to be the caloric loss resulting from enhanced glucose excretion.[134] See Chapter 40 for a detailed discussion of diabetes treatment, use of these medications, and their mechanism of action.

Bariatric Surgery

Surgery remains the most effective means of inducing significant weight loss in individuals with extreme obesity. In addition, bariatric surgery-induced weight loss is effective in reducing obesity-related comorbidities, and a benefit on overall and cause-specific mortality has also been demonstrated.[135]

The National Institutes of Health established guidelines for the surgical treatment of obesity in 1991.[136] Eligible patients with a BMI greater than or equal to 40 kg/m^2 should be well-informed and motivated. In addition, they should have demonstrated an inability to lose weight with conventional therapy and have acceptable operative risks. Adults with a BMI greater than or equal to 35 kg/m^2 with a serious comorbidity including T2DM, hypertension, cardiomyopathy, sleep apnea, or severe joint disease may also be surgical candidates. There is increasing evidence to suggest that surgery may be beneficial for patients with a BMI of 30 to 35 kg/m^2 who have T2DM.[135] Bariatric surgery should be performed in conjunction with a comprehensive follow-up plan consisting of nutritional, behavioral, and medical monitoring.

There are several mechanisms that have been proposed for how bariatric surgery induces weight loss and improves comorbidities beyond its effect to reduce caloric intake. See Chapter 27 for a detailed discussion of bariatric surgery techniques, mechanisms, and outcomes.

KEY POINTS

- Lifestyle modification is the first-line treatment for overweight/obesity. Pharmacologic treatment and bariatric surgery should be used in conjunction with lifestyle modification for best outcomes. Weight loss has a significant ability to decrease comorbidities associated with excess adiposity.

Acknowledgments

The authors would like to acknowledge Jose Caro, Michael Cowley, and Wendy A. Brown for their work on this chapter in previous editions.

INTRODUCTION

While hyperphagia (increased food intake) and weight gain of short duration should prompt investigation for space-occupying lesions of the hypothalamus, sustained hyperphagia and obesity from early childhood are common features of the genetic obesity syndromes. Some disorders are associated with learning difficulties, developmental delay, and other overt clinical problems that bring children to medical attention at a young age. However, over the last 20 years there has been increasing recognition that there are a group of genetic disorders where severe obesity alone is the presenting feature. The molecular and clinical characterization of these monogenic obesity syndromes has informed our understanding of the function of the leptin-melanocortin pathway in the hypothalamus that regulates appetite and body weight, and as a result some of these disorders can now be treated.

Leptin was first discovered by studying severely obese *ob/ob* mice that were found to be lacking a hormone produced by adipose tissue.[1] Administration of leptin to these mice reduced their excessive food intake and corrected neuroendocrine and metabolic abnormalities, proving that leptin is a pivotal regulator of energy homeostasis.[2-4] Subsequent work by Ahima and Flier[5] showed that leptin's physiological role is to signal nutritional depletion, such that fasting or weight loss result in a fall in leptin levels, which then trigger an increase in energy intake and reduced energy expenditure to maintain energy homeostasis.

The physiological effects of leptin are mediated through the central nervous system, particularly the hypothalamus, where the long signaling isoform of the leptin receptor is highly expressed.[6] Leptin binding to its receptor phosphorylates the transcription factor STAT3, which dimerizes and translocates to the nucleus, where it stimulates the expression of proopiomelanocortin (POMC) (Fig. 21.1). POMC is posttranslationally processed to yield the melanocortin peptides (alpha, beta, and gamma melanocyte-stimulating hormone [MSH]), which are agonists with varying affinities for the melanocortin 3 receptor (MC3R) and melanocortin 4 receptor (MC4R) expressed on second-order neurons.[7] In the fed state, leptin stimulates the expression of POMC and the firing of POMC neurons; POMC-derived peptides activate MC4R to decrease food intake. Perhaps even more importantly, leptin suppresses the activity of neurons expressing AGRP, a peptide that antagonizes signaling at MC3R and MC4R. In addition to leptin, the POMC and AGRP neurons also respond to other signals of nutritional status such as insulin, ghrelin, and certain amino acids. Genetic disorders that directly or indirectly disrupt this pathway can cause hyperphagia and weight gain (Table 21.1). As these neurons project to and receive inputs from other brain regions, disruption of the leptin-melanocortin pathway can affect a range of behaviors, neuroendocrine function, and autonomic function, and thereby blood pressure and insulin secretion.

MONOGENIC OBESITY SYNDROMES

Congenital Leptin and Leptin Receptor Deficiency

Homozygous (and compound heterozygous) loss-of-function mutations in the genes encoding leptin (*LEP*) and the leptin receptor (*LEPR*) cause rapid weight gain in the first few months of life, resulting in severe obesity.[8,9] Children develop intense hyperphagia with food-seeking behavior and find all types of food very rewarding.[10] Although no changes in resting metabolic rate or total energy expenditure are detectable, abnormalities in sympathetic nerve function have been reported.[11] Leptin and leptin receptor deficiency are associated with hypothalamic hypothyroidism and hypogonadotropic hypogonadism.[12,13] However, some evidence for the delayed but spontaneous onset of menses has been reported in adults.[14] Children have impaired T-cell number and function, consistent with high rates of childhood infection and a high rate of childhood mortality.[13,15]

Congenital leptin deficiency can be diagnosed on the basis of undetectable serum leptin concentrations; a small number of mutations that result in detectable levels of leptin that is bioinactive have been reported.[16] Serum leptin levels are not elevated disproportionately in *LEPR* deficiency, although particular mutations located near

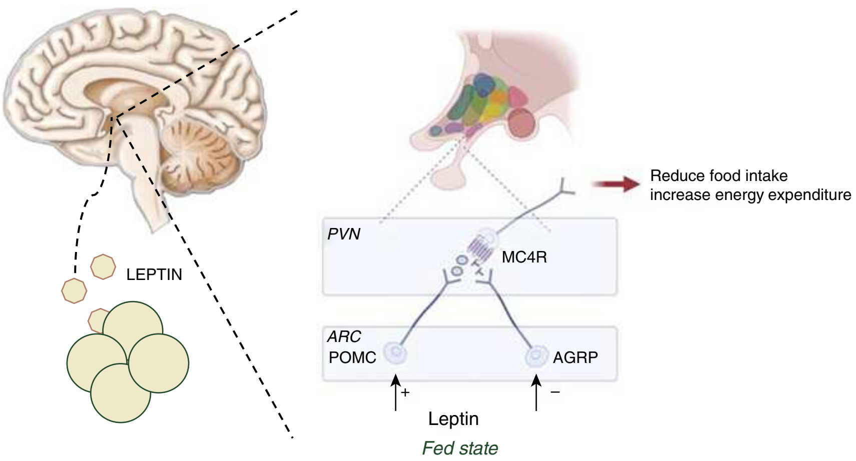

Fig. 21.1 Leptin regulates body weight through the melanocortin pathway. Leptin is secreted by adipocytes and acts on neurons in the hypothalamus. In the fed state, leptin stimulates primary neurons in the arcuate nucleus (ARC) of the hypothalamus that express proopiomelanocortin (POMC). POMC-derived peptides act on the melanocortin 4 receptor (MC4R) expressed on neurons in the paraventricular nucleus (PVN) to reduce energy intake. At the same time, leptin inhibits neurons expressing Agouti-related peptide (AGRP), which antagonizes melanocortin receptors.

TABLE 21.1 Monogenic Obesity Syndromes

Gene Affected	Inheritance	Additional Clinical Features
Leptin	Autosomal recessive	Severe hyperphagia, frequent infections, hypogonadotropic hypogonadism, mild hypothyroidism
Leptin receptor	Autosomal recessive	Severe hyperphagia, frequent infections, hypogonadotropic hypogonadism, mild hypothyroidism
Proopiomelanocortin	Autosomal Recessive	Hyperphagia, cholestatic jaundice or adrenal crisis due to adrenocorticotropic hormone deficiency, pale skin and red hair
Prohormone convertase 1	Autosomal recessive	Small bowel enteropathy, postprandial hypoglycemia, hypothyroidism, adrenocorticotropic hormone deficiency, hypogonadism, central diabetes insipidus
Carboxypeptidase E	Autosomal recessive	
Melanocortin 4 receptor	Autosomal dominant	Hyperphagia, accelerated linear growth
Single-minded 1	Autosomal dominant	Hyperphagia, accelerated linear growth, speech and language delay, autistic traits
Brain-derived neurotropic factor	Autosomal dominant	Hyperphagia, developmental delay, hyperactivity, behavioral problems including aggression
TRKB	Autosomal dominant	Hyperphagia, speech and language delay, variable developmental delay, hyperactivity, behavioral problems including aggression
SH2B1	Autosomal dominant	Hyperphagia, disproportionate hyperinsulinemia, early type 2 diabetes mellitus, behavioral problems including aggression

the transmembrane domain can result in a truncated extracellular domain that binds leptin, resulting in abnormally elevated leptin levels.[17] Sequencing of *LEP* and *LEPR* is therefore indicated in very severe obesity that begins in the first year of life, even when leptin levels are normal.

Treatment of leptin deficiency with recombinant leptin results in a dramatic improvement in hyperphagia, weight loss, and correction of thyroid and T-cell dysfunction[15,8] (Fig. 21.2). Leptin treatment permits progression of appropriately timed pubertal development, suggesting that leptin is a permissive factor for the development of puberty.[13,15] Leptin may exert these effects on the reproductive system through a number of molecules, including kisspeptin, which signals through GPR54 to modify the release of gonadotropin-releasing hormone. Linear growth is normal in childhood; however, due to the absence of a pubertal growth spurt, final height appears to be reduced if patients are not treated.[14] Until recently, LEPR deficiency was not treatable. However, trials of the MC4R agonist setmelanotide have shown promising results, with suppression of hunger and weight loss[19]; this medication has been licensed for the treatment of LEPR deficiency in the US.

Proopiomelanocortin and PCSK1 Deficiency

The POMC precursor peptide is posttranslationally processed into multiple peptides, in a tissue-specific manner. In the pituitary gland, POMC is cleaved to yield adrenocorticotropic hormone (ACTH). In the skin, the POMC-derived melanocortin peptides α- and β-MSH regulate pigmentation by signaling through the melanocortin 1 receptor (MC1R), and in the brain, α- and β-MSH activate signaling via MC4R to reduce food intake (Fig. 21.3). As a result, homozygous or compound heterozygous mutations in *POMC* lead to hyperphagia and early-onset obesity, isolated ACTH deficiency (presenting as neonatal hypoglycemia), and hypopigmentation of skin and hair, which is more noticeable in people of European ancestry.[20,21] Heterozygous null mutations in *POMC* and loss-of-function mutations in the part of the *POMC* gene that encodes α- and β-MSH significantly increase obesity risk but are not invariably associated with obesity.[22,23]

The POMC propeptide is processed into its active melanocortin products by a series of enzymes that are differentially expressed in the hypothalamus and the pituitary. Prohormone convertase 1 (PCSK1) is necessary for the production of ACTH and is highly expressed in the pituitary. The hypothalamus, but not the pituitary, expresses a related

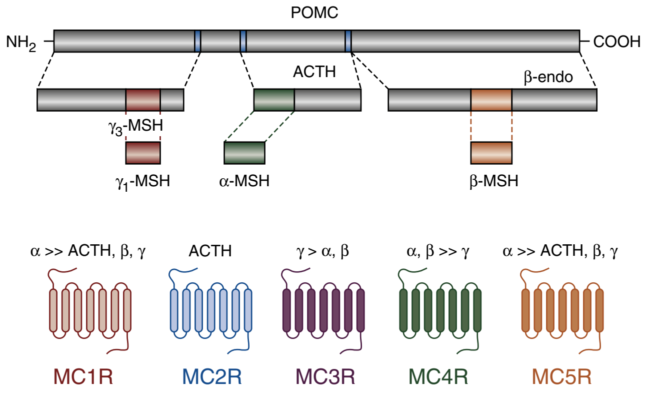

Fig. 21.3 Proopiomelanocortin (POMC)-derived peptides and melanocortin receptors. POMC is processed into adrenocorticotropic hormone (ACTH) and α, β, and γ-melanocyte stimulating hormone (MSH) peptides, which act on the melanocortin 1–5 receptors (MC1R–MC5R).

enzyme PCSK2, which acts on the products of the prior PCSK1 cleavage to produce the smaller melanocortin peptides. A further enzyme, carboxpeptidase E, is needed to produce the final mature peptides. Impaired processing of POMC contributes to the hyperphagic severe early-onset obesity and ACTH deficiency in people lacking PCSK1.[24] Hypogonadotropic hypogonadism due to the impaired processing of prepro–gonadotropin-releasing hormone and postprandial hypoglycemia due to impaired processing of proinsulin to insulin are additional clinical features. Where these assays are available, the finding of high proinsulin levels in the context of a low plasma insulin can point to this diagnosis. Impaired processing of gut-derived peptides in the enteroendocrine cells that express PCSK1 throughout the gut[25] may contribute to neonatal enteropathy; indeed, patients may first present to gastroenterologists with these symptoms. A single family with a homozygous mutation in carboxypeptidase E with overlapping clinical features has also been reported.[26] Setmelanotide has been shown to be effective in POMC and PCSK1 deficiency[27,28] and has been licensed for chronic weight management in these disorders in the United States.

MC4R Deficiency

POMC-derived peptides act as agonists at the MC4R. Targeted disruption of *Mc4r* in mice leads to increased food intake, weight gain, increased lean mass, and linear growth.[29] Heterozygous loss-of-function mutations in *MC4R* are found in 5% to 6% of patients with severe early-onset obesity[30,31] and at a frequency of approximately 1/330 in the general UK population, making this the commonest gene in which variants contribute to obesity. Most naturally occurring disease-causing MC4R mutations disrupt the expression and trafficking of the receptor to the cell surface.[32] The mechanism of G protein–coupled receptor (GPCR) dysfunction has potential interest, as pharmacological chaperones can increase the cell surface expression and signaling of mutant GPCRs, which represents a rational therapeutic approach for this condition.[33] Additionally, mutations can affect the production of cyclic adenosine monophosphate, the homodimerization of MC4R, the endocytosis of MC4R, and the recruitment of β-arrestins.[34]

MC4R mutations are inherited in a codominant manner, with variable penetrance and expression in heterozygous carriers[30]; less commonly, homozygous and double heterozygous (different mutations on both alleles) mutations have been reported in patients with severe obesity. The features of MC4R deficiency include hyperphagia, hyperinsulinaemia, increased lean mass, and increased linear growth.[30,35]

Complete loss-of-function mutations have a larger impact on phenotype than partial loss-of-function mutations.[36]

MC4R$^{-/-}$ mice maintain a normal blood pressure despite severe obesity.[37] Similarly, loss-of-function MC4R mutations in humans are associated with a reduced prevalence of hypertension, low systolic blood pressure, lower urinary noradrenaline excretion, and reduced peripheral nerve sympathetic activation compared with similarly obese people without MC4R mutations.[38,39] As MC4R neurons synapse with preganglionic sympathetic neurons, which regulate vascular tone, increased signaling through MC4R can lead to an increase in blood pressure, as seen with first-generation melanocortin receptor agonists given to obese volunteers. Setmelanotide, a second-generation MC4R agonist that causes weight loss without increasing blood pressure, has been shown to be very effective in POMC and PCSK1 deficiency and is currently being trialed in heterozygous MC4R deficiency. Liraglutide, the GLP-1 receptor agonist, is effective in some patients with MC4R deficiency,[40] and some patients with heterozygous (but not homozygous) mutations benefit from Roux-en-Y-bypass surgery.[41]

SIM1 Deficiency

SIM1 is a transcription factor that plays a key role in the development and function of the paraventricular nucleus of the hypothalamus, where MC4R is highly expressed. Dominantly inherited or *de novo* deletions of chromosome 6q14-21 that encompass the *SIM1* gene, as well as heterozygous loss-of-function *SIM1* mutations,[42,43] cause hyperphagia, severe obesity, and relatively low systolic blood pressure, features that closely overlap with those seen in MC4R deficiency. Many SIM1 mutation carriers have speech and language delay in childhood and exhibit neurobehavioral abnormalities, including autistic-type behaviors. These features show some overlap with the behavioral phenotypes seen in Prader–Willi syndrome (PWS). Expression of the neuropeptide oxytocin is reduced in mouse models of Sim1 deficiency, and oxytocin administration reduces food intake in *Sim1*-haploinsufficient animals.[44] As oxytocin is involved in energy homeostasis, emotional responses, and social interaction, reduced levels of oxytocin may contribute to the behavioral phenotype seen in SIM1 deficiency. A reduced number of oxytocin neurons and reduced oxytocin mRNA and protein levels have also been reported in PWS.[45,46] For this reason, some reports have referred to SIM1 deficiency as being PWS-like. A small number of mutations in OTP, another transcription factor involved in paraventricular nucleus development, have been reported in patients with obesity and autistic behaviors.[47]

BDNF, TRKB, and SH2B1 Deficiency

Chromosome 11p.12 deletions encompassing the brain-derived neurotrophic factor (*BDNF*) gene[48] or missense mutations that disrupt *BDNF* or its tyrosine kinase receptor, tropomycin-related kinase B (TrkB), are associated with hyperphagia and obesity.[49] Mutations often arise *de novo,* and as such should be considered where both parents are of normal weight and IQ. The neurotrophin BDNF is widely expressed in the brain and signals via TrkB to regulate neuronal differentiation and survival, synapse formation, and activity-dependent changes in synapse structure and function. BDNF and TrkB are expressed in areas of the brain involved in learning and memory, including the hippocampus. Obesity-associated mutations that impair TrkB signaling affect dendritic spine structure and function, which forms the neural substrate for learning and memory in hippocampal neurons.[49] In addition to severe obesity, carriers of these functional TrkB mutations have learning difficulties, impaired short-term memory, hyperactivity, repetitive behaviors often considered to be autistic-like, fearlessness, and in some cases aggression. Some of these neurobehavioral phenotypes, as well as increased locomotor activity, have been observed in animal models of *Bdnf/Trkb* disruption.[50]

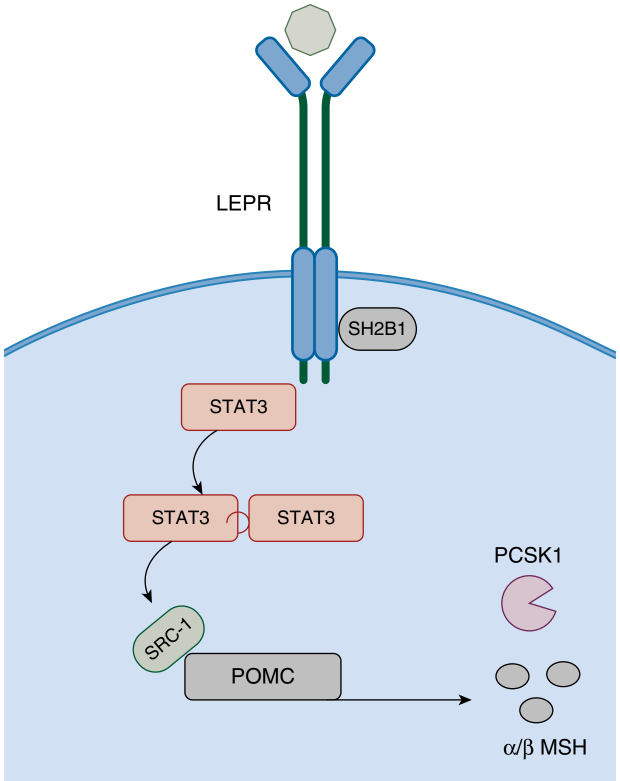

Fig. 21.4 Genes that modulate leptin signaling to cause obesity. Leptin signaling through its receptor (LEPR) is enhanced by SH2B1 and results in the activation of STAT3, which dimerizes and translocates into the nucleus to activate proopiomelanocortin (*POMC*) transcription. SRC-1 modulates *POMC* transcription by interacting with activated STAT3. POMC is processed by PCSK1 to yield the melanocortin peptides (α and β-MSH).

Src-homology-2 (SH2) B-adaptor protein-1 (SH2B1) is an intracellular adaptor protein that mediates signaling through a number of receptor tyrosine kinases (including TrkB) and cytokine receptors (including the leptin receptor) (Fig. 21.4); mutations impair signaling and neurite differentiation. Chromosomal deletions on 16p11.2 that include SH2B1[51] and heterozygous mutations in the gene itself[52] are associated with hyperphagia, dominantly inherited severe early-onset obesity, and disproportionate insulin resistance. Male mutation carriers often have behavioral problems, including social isolation and aggressive behavior from childhood.[52,53] Intriguingly, mice with brain-specific deletion of *Sh2b1* gain weight and develop reactive aggression[54]; brain-specific restoration of Sh2b1 completely reverses intermale aggression. Neural SH2B1 promotes brain development and growth, at least in part by enhancing the actions of BDNF and related neurotrophic factors.

PLEIOTROPIC OBESITY SYNDROMES

In a number of syndromes, obesity is one of a number of features (pleiotropic) alongside developmental/learning difficulties and dysmorphic features (Table 21.2). A number of these disorders arise from chromosomal abnormalities.

Prader–Willi Syndrome

PWS is relatively common, with an estimated prevalence of 1 in 25,000 births,[3] and is characterized by diminished fetal activity, hypotonia,

TABLE 21.2 Pleiotropic Genetic Obesity Syndromes

Syndrome	Inheritance	Additional Clinical Features
Prader–Willi	Autosomal dominant	Hypotonia, failure to thrive in infancy, developmental delay, short stature, hypogonadotropic hypogonadism, sleep disturbance, obsessive behavior
Albright's hereditary osteodystrophy	Autosomal dominant	Short stature in some, skeletal defects, developmental delay, shortened metacarpals; hormone resistance when mutation is on maternally inherited allele
Bardet–Beidl	Autosomal recessive	Syndactyly/brachydactyly/polydactyly, developmental delay, retinal dystrophy or pigmentary retinopathy, hypogonadism, renal abnormalities
Cohen	Autosomal recessive	Facial dysmorphism, microcephaly, hypotonia, developmental delay, retinopathy
Carpenter	Autosomal recessive	Acrocephaly, brachydactyly, developmental delay, congenital heart defects; growth retardation, hypogonadism
Alstrom	Autosomal recessive	Progressive cone-rod dystrophy, sensorineural hearing loss, hyperinsulinemia, early type 2 diabetes mellitus, dilated cardiomyopathy, pulmonary, hepatic and renal fibrosis
Tubby	Autosomal recessive	Progressive cone-rod dystrophy, hearing loss

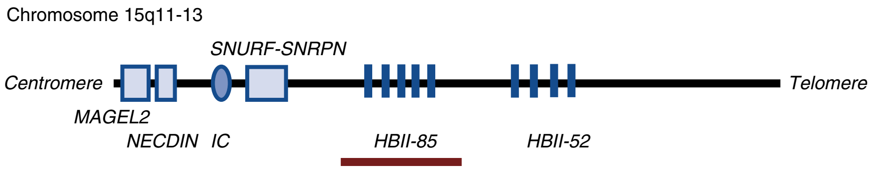

Fig. 21.5 **Chromosomal deletion in Prader–Willi syndrome (PWS).** Paternal chromosome 15q11-13 deletions cause PWS. A number of genes (*MAGEL2*, *NECDIN*), small nuclear ribonucleoprotein polypeptide N (*SNRPN*), and the imprinting center (IC) are deleted in most patients, but the minimal critical region involved in the phenotype involves the HBII-85 snoRNAs (noncoding small nucleolar RNAs).

developmental delay, short stature, hypogonadotropic hypogonadism, and obesity. PWS is caused by deletion of an imprinted region on the paternal chromosome 15q11-q13. Loss of the entire paternal chromosome 15 with the presence of two maternal homologs (uniparental maternal disomy) occurs in approximately 20% of patients. While a number of genes within the imprinted region have been studied, small deletions restricted to a family of noncoding RNAs (HBII-85 snoRNAs) recapitulate the classical features,[55,56] providing strong evidence that these noncoding RNAs play a causal role in PWS (Fig. 21.5). These noncoding RNAs affect the alternative splicing of a large number of target genes, with evidence of intron retention,[46] as is also seen in a number of neurodegenerative diseases. RNA sequencing of brain tissue from PWS patients has shown that expression of BDNF and its receptor TrkB is reduced, and downregulated genes affect neuronal differentiation, maintenance, and synaptic plasticity.[46] Neuroimaging studies in PWS have identified reduced gray matter volume in cortical areas and abnormal gyrification.[57] As such, it is likely that the complex clinical phenotype arises from the reduced expression of large number of genes in the hypothalamus and other brain regions.

Patients often have low birth weight at term (in keeping with other imprinted disorders) and poor feeding as neonates due to diminished swallowing and sucking reflexes, which may require assisted feeding for 3 to 4 months. Feeding difficulties generally improve by the age of 6 months. From 12 to 18 months, hyperphagia is a dominant feature in children with PWS, often associated with pica behavior. One suggested mediator of the obesity phenotype in PWS patients is the enteric hormone ghrelin, which is implicated in the regulation of mealtime hunger and also stimulates growth hormone (GH) secretion via the GH secretagogue receptor. Fasting plasma ghrelin levels are 4.5-fold higher in PWS subjects than in equally obese controls and patients with other obesity syndromes[58]; whether this finding is relevant in the pathogenesis of hyperphagia in these patients remain unclear. The mainstay of management has centered on low-calorie diet with regular exercise, rigorous supervision, restriction of food, and behavioral counseling for the patient and family, often in the context of group homes for PWS adolescents and adults.

Children with PWS have reduced linear growth, reduced muscle mass, and increased fat mass, body composition abnormalities that are consistent with GH deficiency. Treatment with GH significantly improves growth and final height, and GH is licensed for use in PWS. GH treatment also decreases body fat and increases muscle mass.[59] Gonadal maturation is delayed or incomplete as the result of hypogonadotropic hypogonadism.

Albright's Hereditary Osteodystrophy

Albright's hereditary osteodystrophy (AHO) is an autosomal dominant disorder caused by heterozygous loss-of-function mutations in *GNAS*, the gene encoding Gα_s (stimulatory G-protein alpha subunit), which mediates GPCR signaling. Patients present with developmental delay, brachydactyly (shortened metacarpals and/or metatarsals), subcutaneous ossifications, childhood-onset obesity with short adult stature (height below the 3rd percentile for chronological age), and in some cases hormone resistance syndromes.[60-62] Imprinting at the *GNAS* locus results in selective silencing of the paternally-inherited *GNAS* allele in some tissues. Patients with mutations on maternally-inherited alleles, which are preferentially expressed in the thyroid, pituitary, and renal proximal tubule, develop resistance to parathyroid hormone and other hormones that signal through Gα_s-coupled receptors (pseudohypoparathyroidism type 1A),[61] while patients with mutations on paternally-inherited alleles have AHO without hormone resistance (pseudopseudohypoparathyroidism [PPHP]).

Obesity is a well-recognized feature of PHP when mutations occur on the maternally inherited *GNAS* allele. Studies in patients presenting with severe childhood-onset obesity have revealed an unexpectedly high prevalence of *GNAS* mutations, indicating that screening for mutations in *GNAS* should be incorporated into the diagnostic workup of severe childhood-onset obesity.[63] Early diagnosis guides monitoring for hormone resistance syndromes, recognition of hypocalcemia as a cause of seizures, and treatment with thyroxine and with recombinant human GH before fusion of the growth plate.[62,64]

Brain-specific deletion of the maternal Gα_s allele impaired the ability of an MC4R agonist to reduce body weight, suggesting a role for centrally expressed MC4Rs in mediating obesity in *GNAS* deficiency.[65] Recent studies have shown that obesity-associated missense mutations in *GNAS* impair MC4R signaling.

Bardet–Biedl Syndrome

Bardet–Biedl syndrome (BBS) is an autosomal recessive syndrome characterized by obesity, developmental delay, syndactyly, brachydactyly or polydactyly, retinal dystrophy or pigmentary retinopathy, hypogonadism, and renal abnormalities. BBS is genetically very heterogeneous, with mutations in at least 20 genes reported to date and evidence of triallelic inheritance in some families (two mutations in one BBS gene plus an additional mutation in a second, unlinked BBS gene).[66] Most of the genes involved in BBS affect the structure and/or function of the basal body, a modified centriole that is essential for the function of nonmotile cilia.[67] There is some evidence that BBS proteins affect leptin signaling, and as such the MC4R agonist setmelanotide (which targets the MC4R pathway downstream of leptin) has been trialed in these patients, with some success.[68]

Alstrom Syndrome

Alstrom syndrome shows some overlap with BBS (retinitis pigmentosa, deafness, obesity, diabetes mellitus with recessive inheritance); however, classically, developmental delay, polydactyly, and hypogonadism are not features. Patients present with a severe visual defect in infancy, photophobia, nystagmus, and loss of central vision. Some affected individuals present with dilated cardiomyopathy (often diagnosed in infancy), hepatic dysfunction, renal dysfunction, hypothyroidism, male hypogonadism, short stature, and mild to moderate developmental delay.[69]

Although obesity is common in this syndrome, it is rarely severe. In contrast, insulin resistance due to impaired adipose tissue expandability[70] is frequently severe, and once diabetes develops, it may be very difficult to control. Hypertriglyceridemia may be severe and may result in acute pancreatitis. Mutations in *ALMS1*, which is localized to the centrosome and the ciliary basal bodies *in vitro*, suggest a role in the structure of the basal body or in the transport of proteins between the cytoplasm and the ciliary axoneme.

Cohen Syndrome

Cohen syndrome is an autosomal recessive disorder characterized by nonprogressive mild to severe psychomotor retardation, motor clumsiness, microcephaly, characteristic facial features, childhood hypotonia, intermittent isolated neutropenia, and a cheerful disposition. Progressive, often high-grade myopia and retinochoroidal dystrophy resembling retinitis pigmentosa are essential features in Cohen syndrome.[71] Vision starts to deteriorate early but generally is preserved until adulthood, and by the age of 40 years many patients are severely visually impaired. Mutations in *COH1* found in some Finnish patients with Cohen syndrome suggest a role in intracellular vesicle–mediated sorting and transport, although the link to obesity has not been established.

KEY POINTS

- Monogenic obesity syndromes are characterized by hyperphagia (increased drive to eat) and weight gain that begins before the age of 5 years. Disorders affect hypothalamic pathways involved in the regulation of hormone secretion, and as such patients sometimes have endocrine features such as hypogonadism. Genetic obesity syndromes that affect neural development can be associated with developmental delay and behavioral difficulties.

RARE VARIANTS ASSOCIATED WITH OBESITY

In addition to these dominant or recessively inherited monogenic obesity syndromes, there is increasing recognition that variants in a broader set of genes contribute to severe obesity. As these variants are rare, statistical evidence of enrichment in obese cases versus controls is often not achieved (power calculations predict that studies involving hundreds of thousands of patients would be needed[72]). While patients in whom these variants are described often share a set of clinical features, severe obesity is often not inherited in a classical Mendelian manner, and there can be incomplete penetrance and variable expressivity within and across families. Nonetheless, where variants cause a loss of function in cells, affect a mechanism known to regulate weight, and/or cause obesity when modeled in mice, there is sufficient evidence to indicate that rare obesity-associated variants contribute to the missing heritability in obesity, as seen for other complex traits.[73] Where the molecules encoded by these genes converge on pathways known to be involved in weight regulation, there is sometimes sufficient evidence to treat subsets of patients.

The semaphorin 3s are a large family of secreted proteins that have both repulsive and attractive effects on axons during development.[74] Recent evidence in mice has shown that SEMA3A guides vomeronasal neurons, which migrate into the hypothalamus to develop into gonadotropin-releasing hormone–expressing cells, and loss-of-function variants contribute to hypogonadotropic hypogonadism in a non-Mendelian manner. Semaphorin 3s acting via the neuropilin-2 receptor direct the development of the melanocortin circuit formed by POMC projections extending from the arcuate to the paraventricular nucleus of the hypothalamus.[75] Rare loss-of-function variants in semaphorin 3 ligands, receptors, and coreceptors are enriched in severely obese individuals compared with controls.[75] Some individuals had learning difficulties, behavioral abnormalities, and neurological disorders including epilepsy, as well as medication-resistant constipation in childhood. SEMA3 signaling is known to regulate the development of the enteric nervous system, and rare heterozygous loss-of-function variants in *SEMA3C* and *SEMA3D* have been associated with Hirschsprung disease,[76] a disorder characterized by failure of development of parasympathetic ganglion cells in the large intestine.

In the arcuate nucleus of the hypothalamus, leptin signaling leads to the phosphorylation of STAT3, which interacts with the transcription factor steroid receptor coactivator (SRC)-1 to modulate *POMC* transcription (Fig. 21.4). Disruption of the SRC-1-pSTAT3 interaction causes obesity in mice, and rare heterozygous variants in *SRC-1* identified in severely obese people decrease leptin-pSTAT3 mediated signaling and POMC expression in cells.[77] A mouse model of a human loss-of-function SRC-1 variant gains weight on a high-fat diet. As a result of this evidence, trials are ongoing to investigate whether patients with SRC-1 deficiency may lose weight with setmelanotide.

Nuclear pleckstrin homology domain–interacting protein (PHIP) directly affects the transcription of POMC, and obesity-associated PHIP mutants have been shown to decrease *POMC* transcription.[78] Heterozygous *PHIP* deletions and frameshift mutations have been reported in patients with developmental delay, intellectual disability, dysmorphic features, and in some cases obesity.[79] The absence of severe obesity in some family members carrying *PHIP* loss-of-function variants, as well as the presence of missense variants in control participants without obesity, suggests variable penetrance. In keeping with the growth phenotype seen in null mice, some, but not all, *PHIP* variant carriers exhibit low birth weight, reduced linear growth in childhood, hyperphagia, insulin resistance, and early type 2 diabetes.

Rare variants in the gene encoding MRAP2, an accessory protein that interacts with MC4R and leads to obesity when disrupted in mice, have been associated with severe obesity, although the detailed molecular mechanisms underlying this association are not known.[80]

To date, most of the genetic obesity syndromes are characterized by hyperphagia as the major driver of the obesity. Loss-of-function mutations in kinase suppressor of Ras2 (*KSR2*) increase food intake but are predominantly associated with reduced basal metabolic rate in the presence of normal thyroid function.[81] Some *KSR2* mutation carriers experience marked weight loss in childhood when prescribed the antidiabetic drug metformin (for severe insulin resistance). Further work will be needed to see if these observations can be replicated and to investigate the cellular mechanisms underlying these effects.

KEY POINTS

- Rare variants that disrupt the function of key genes involved in weight regulation can contribute to severe obesity. Patterns of inheritance may not be clearly Mendelian (e.g., dominant or recessive), with variable penetrance within and between families. Nonetheless, some of these disorders are treatable.

CONCLUSIONS
